- *Concrete pumps*—Three separate systems are combined together in Table 19.2 under the “concrete pump” category for Alternative 1: (1) stationary pump, (2) pipeline, and (3) climbing placing boom. This is specialized equipment commonly procured on a rental basis. In this case, transportation to the site, as well as erection and dismantling, were incorporated by the pump rental company within the monthly rate. The pump is brought to the site and the climbing boom system is installed in the building only after the first floors have been completed (see Figure 19.2). Thus, erection is assisted by the tower crane already on-site and so is dismantling. The service of the truck-mounted pump in Alternative 2 is procured on a quantity basis, but other rate systems are available. In the quantity-based rate system, there is commonly a fixed pumping rate for an initial concrete quantity plus a rate for each additional volume unit (cu yd). To estimate costs, therefore, the number of times the pump will be needed on site and the average concrete placing quantity on each time are assessed.
- *Forming systems*—As clearly evidenced from the costs in Table 19.2, the crane-independent automatic climbing wall-forming system used in Alternative 1 symbolizes industrialization more than any other single equipment used in the example project. Not only does it save precious crane time (which, together with the concrete pump, allows for the use of one crane only on the high-rise structure), but it also makes an enormous difference in terms of labor power needed on the project. The high cost of labor in Alternative 2 is due mainly to the much lower production rates achieved with manual forming as compared to the automatic system in Alternative 1, but

TABLE 19.3 Typical Soft Equipment Selection Factors

Factor	Explanation/Examples
Company policy toward own vs. rent	“Own” policy may result in purchasing equipment that, with a view to future projects, exceeds the requirements of a particular project, whereas “rent” policy is likely to produce a solution catering to the exact needs of that project only. Similarly, preference may be given to the use of owned, currently unemployed equipment (e.g., two small cranes) over rented equipment (e.g., one large crane), even if the latter would have otherwise been the optimal solution. Companies would generally look first into using their own equipment before other options are considered, even if cost comparisons would point to a rental-based solution.
Company project forecast	This factor influences current purchase vs. rent decisions and thus may affect the equipment selected for a particular project under discussion. It has a bearing on costs through the value given to the predicted return period in economic calculations.
Commercial considerations	The desire to start operating part of the constructed facility (in case of a cash-flow-producing asset) earlier than the rest of it may affect equipment selection (e.g., refraining from locating tower crane in underground parking of an office building if it may interfere with the early operation of the parking as a public facility before the main building was completed).
Procurement method and subcontracting	Quite often, the client/owner dictates certain requirements that affect equipment selection (e.g., using the client’s given equipment, providing craning services to other contractors on the same project, or forbidding the use of certain zones for locations of equipment). Another case example is of a joint venture project where the two construction companies decide to have identical equipment on site to simplify accounting between them (e.g., two cranes), even if another solution (e.g., a crane and a concrete pump) may otherwise be favored.
Company project specialization	A company may specialize in certain categories of construction (e.g., high-rise buildings, precast structures). This is reflected in the equipment it owns and operates and can have direct implications on the equipment available for a new project. It also influences the type, experience, and size of the company’s equipment maintenance department, which, in turn, affects cost estimates.
Dependence on outsourcing	Outsourcing increases dependence on factors outside the site management control, chances of mishaps, and uncertainty in general. Avoiding it may lead, for example, to favoring on-site plant for the fabrication of precast elements over ordering them externally.
Shifting responsibility to external party	Favoring ready-mixed concrete over on-site concrete production or favoring the ordering of precast elements over on-site fabrication has an advantage in terms of quality assurance of the product as well as contractual liability to this quality.
Working night shifts	Night shifts commonly result from either a tight schedule or traffic-induced difficulties in transporting concrete/precast elements to the site during the daytime. It may affect site management and is also an additional cause for safety concerns. Obviously, it incurs higher wages, which are reflected in the cost estimates.

also to the need to work at night, when wages are much higher. The forms rental company that provides the automatic system and supervises its erection includes transportation costs for most parts of the system in the monthly rate. Erection and dismantling are carried out by the construction company workforce and their costs are included in labor wages. As for the forms used in Alternative 2, they are owned by the construction company and have exceeded their nominal useful life.

19.2.3 Soft Considerations

If equipment alternatives were compared based on costs only, then, for example, Alternative 1, considerably less costly than Alternative 2, would be the one selected for the above-exemplified project. As mentioned earlier, however, the great variety of qualitative and intangible factors, if considered, may

TABLE 19.3 (cont.) Typical Soft Equipment Selection Factors

Factor	Explanation/Examples
Tradition, previous experience	The types of equipment selected for the project may be heavily affected by experience and by tradition, whether on the market level (availability of technical support), company level (culture), or site management level (personal preferences). The same applies for the location of equipment (e.g., internal climbing crane or climbing placing boom located in the elevator shaft or elsewhere in the floor through openings in the slabs).
Redundancy of equipment	The need to have backup for contingencies (e.g., breakup of a machine) so as to avoid work stoppage may give advantage to using multipurpose equipment or excess equipment.
Obstacles on site	Obstacles commonly include overhead power lines and adjacent structures, which can affect productivity and safety. Fixed (rather than mobile) equipment may have an advantage; specialized operator aids may be required.
Labor availability	Labor shortage increases the attractiveness of higher mechanization in general and automated systems in particular. This goes beyond the need to pay higher wages, which should be taken fully into account in the cost estimates. Temporary unavailability of skilled laborers may impede work progress severely.
Noise levels	Give preferences to electric over diesel powered equipment; noise levels may also exclude night work.
Site accessibility	Narrow roads may limit the size of precast concrete elements or steel trusses transported to the site, which in turn may affect equipment size requirements (e.g., a greater number of smaller machines).
Heavy traffic	For projects located in urban areas near congested roads, heavy reliability on a continuous external supply (e.g., of ready-mixed concrete in large volumes overall) may be abandoned in favor of on-site production, even if the latter is much costlier (e.g., if the constructed facility takes up the entire area of the site, necessitating relocation of an on-site concrete production plant several times during construction). Night work is another solution (but it may have been reserved for supply of other materials/elements, such as precast panels).
Strong winds	In areas given to strong winds, tower cranes may be preferred over mobile cranes. Additionally, the use of forming systems that climb automatically without crane assistance may be considered to avoid craning of large forms that act like a sail.
Equipment age and reliability	Technological advantages aside, newer equipment is likely to encounter fewer operational problems and less downtime, thus offering better service overall.
Overlapping of crane work envelopes	Overlapping tower cranes often are unavoidable, whether because of reach limits or daily schedule demands. Careful work and designation of forbidden zones helps in coping with safety hazards, but work may be slowed down. The use of (costly) anticollision systems may be considered.
Obstruction of crane operator view	Even with signal persons, this could become a major safety hazard (lower productivity is another result), and hence should be taken into account when equipment selection and location alternatives are considered. Operator vision aids (e.g., crane-mounted cameras) offer a partial solution.

point to the solution offered by Alternative 2, which otherwise is costlier. Alternatively, these factors may consolidate the selection of Alternative 1, as was made on economic grounds only. Certainly, if Alternatives 1 and 2 showed near enough the same costs, then the decision as to which one to select would depend entirely on adequate assessment of these qualitative and intangible factors. Table 19.3 offers a list of typical such “soft” factors, as these are usually termed (Shapira and Goldenberg, 2007). The following points are common to most soft factors:

- They are strongly connected to local cultures and traditions, as well as to the physical, organizational, and market environment. They express the uncertainty and intuition rooted in construction decision making, as well as the subjective judgment that is likely in the background of many seemingly pure technical calculations. Their consideration draws from the experience accumulated by the individuals who participate in the decision-making process and in the construction company.

- If they are measurable, they exhibit a great variety of measurement units, which makes it difficult or even impossible to compare them on a common quantitative basis. Only seldom can they be expressed in monetary terms; primarily, they are altogether immeasurable.
- Often the particular decision arrived at by the consideration of one factor is in conflict with that arrived at by another. See, for example, in Table 19.3, “Dependence on outsourcing” and “Heavy traffic” vs. “Shifting responsibility to an external party.” Another example is using mobile cranes owned and readily available by the company vs. using rented tower cranes with which the site superintendent has good experience.
- They affect the initial decision-making process when they are considered, usually intuitively and at times even unconsciously, in the course of the alternative generation phase, alongside hard factors. In many cases, they have a bearing on costs and are taken into account in the cost estimation phase (e.g., see “Company project forecast” and “Company project specialization” in Table 19.3).
- Veteran project managers and other functionaries involved in equipment planning (e.g., equipment managers) may have the rich experience, professional skills, and tacit knowledge it takes to detect all soft factors relevant to the project and to consider them successfully, especially if they operate in a well-developed planning environment. However, the lack of practical tools for the systematic evaluation and consideration of soft factors often results in equipment solutions that eventually are found to be inappropriate or costlier than initially estimated.

It is all these points, and particularly the lack of practical methods and tools to integrate the consideration of soft factors within the entire selection process in a structured and systematic manner, that contribute to the complexity of equipment planning and to the potential realization of inadequate solutions.

A method presented by Shapira and Goldenberg (2005) to deal with this problem is based on a widely accepted multi-attribute decision-making technique referred to as the *analytic hierarchy process* (AHP). AHP, introduced by Thomas Saaty (1980), was developed to assist in the making of decisions that are characterized by a great number of interrelated and often contending factors. To make such decisions, the relative importance of the factors involved must be properly assessed to allow tradeoffs among them. The main feature of AHP is its inherent capability of systematically dealing with a vast number of intangible and nonquantifiable attributes, as well as with tangible and objective factors. AHP allows for incorporation into the decision-making process of subjective judgments and user intuition by producing a common formal and numeric basis for solution.

Recent implementation of the AHP-based equipment selection method to evaluate soft factors and to assess their impact *vis-à-vis* the results of cost comparisons, in a rational process that leads to the selection of a “good” equipment alternative for the project, is demonstrated in detail by Goldenberg and Shapira (2007). The method was examined and tested in real-life settings to satisfying results. The interested reader is referred to Shapira and Goldenberg (2005) to learn about the fundamentals and concepts of the method, and to Goldenberg and Shapira (2007) for an elaborate case study.

19.3 Concrete Equipment

The use of concrete as a building material involves equipment throughout production: from batching and mixing, through transporting and placing, to consolidating and finishing. This section focuses on major equipment commonly used for these operations.

19.3.1 Concrete Mixers

Concrete can be centrally *mixed* in a “wet” plant—a plant that has a built-in mixer—and transported to the site in truckmixers operating at agitating speed, centrally *batched* in a “dry” plant, and mixed in the truckmixer itself, which then drives to the site at agitating speed, or it can be produced on-site. On-site production is a viable solution mainly in case of exceptionally large concrete amounts or if the site is located remotely such that transport distances from the closest plant are too great. The view of a compact

(a)

(b)

FIGURE 19.3 Truckmixers: (a) rear-discharge truckmixer; (b) front-discharge truckmixer.

mobile mixing plant on a small construction site in some parts of the world (e.g., Europe) is not rare; today, this equipment is highly automated, among other things, to ensure high concrete quality control. Where high concrete volumes are required, larger mixing plants with higher outputs are sometimes used on-site—for example, in dense urban areas with access difficulties due to traffic-congested roads. The great majority of today's building sites, however, use ready-mixed concrete delivered to the site from the dry or wet central plant in **truckmixers**, also called *ready-mixed trucks*.

Truckmixers the world over are of the *rear-discharge* type (Figure 19.3a), but in North America, *front-discharge* truckmixers are used as well (Figure 19.3b). The drum in the front-discharge mixer is more elongated. This shape of the drum and the overall configuration of the truck result in a better weight distribution, which allows these trucks to meet road and bridge load restrictions better than the rear-discharge truckmixers. The front-discharge truckmixer allows the driver a more convenient approach to the discharge location; the driver's ability to control the operation from the cab without leaving the cab is an additional advantage in bad weather. This carrier truck, however, is specialized equipment, unlike the standard carrier truck of the rear-discharge mixer, and therefore more costly.

FIGURE 19.4 Truckmixers lined up on the street, awaiting their turn to enter the restricted site and position themselves at the concrete pump.

The drum in the ready-mixed concrete truck, both of the rear- and front-discharge type, is a *freelfall*-type mixer. Freefall mixers blend concrete by lifting the ingredients with the aid of fixed blades inside the rotating drum (in the case of a truckmixer, the blades are spiral) and then letting them drop by gravitation (hence, the term *gravity mixer* is also used for freefall mixers). This is unlike *power* mixers, which blend the concrete by rapid rotary motion of paddles, making them particularly suitable for dry mixes. The drum of the truckmixer is rotated in one direction for loading and in the opposite direction for mixing or agitating (i.e., it is a reversible-type freefall mixer).

When planning a pour with ready-mixed concrete, several points should be considered. The rate of concrete delivery is affected by the size of the truck (namely, the effective intake volume of the drum), distance from the plant to the site, the number of truckmixers allocated by the plant for the specific operation, and possible delays that may be caused by heavy traffic. In terms of site organization, maneuvering space must be ensured for the large and heavy trucks, as well as proper ground conditions for travel. If the site is too restricted to allow free truck movement, as is often the case in mid-city construction sites, provisions should be made to allow for the nearby waiting of trucks. Such operations require thorough planning, workers designated for traffic control, and communication means. Often, one traffic lane would have to be blocked for the duration of the pour, after coordination with the local authorities (Figure 19.4).

Truckmixers come in sizes up to 20 cu yd, with 8 to 12 cu yd being the most common size range. The most popular size appears to be gradually increasing, although it has stabilized at 11 cu yd for several years now. Truckmixers are sometimes equipped with a boom pump or belt conveyor (see below), which gives them greater operational flexibility and independence and can be particularly useful for small jobs (e.g., house renovation) requiring small amounts of concrete.

In Europe, the use of another type of concrete mixing equipment is quite common. This is the **self-propelled mobile mixer**. The compact rough-terrain wheeled carrier, similar to that of the telehandler (see below), carries a self-loading drum-mixer with high-discharge capabilities. Mixer volumes in current models are in the range of 1 to 6 cu yd. Concrete can commonly be discharged with chutes up to 30 ft horizontally and at heights of 3 to 7 ft; with a special hydraulically elevated drum, height discharge can be up to 10 ft. Not used much on building construction sites, this self-contained machine is particularly useful on spread-out, low-rise civil projects, such as long concrete walls, utility lines, or small repair works on airfields, where relatively small quantities of concrete are required at different locations. If aggregates and cement are stored near these locations, the self-loading mixer can travel between them and carry out concrete placing as well. Quite often, such projects are remotely located and are inaccessible to truckmixers. Under such conditions, the use of one machine that offers a solution for aggregate loading and concrete mixing, transporting, and placing is even more attractive.

19.3.2 Concrete Pumps

19.3.2.1 Uses and Outputs

Concrete pumps transport concrete by moving it through a pipeline at high placing rates. As such, a concrete pump is a single-purpose machine—namely, it cannot be the only material transportation equipment on the site (unless concrete is the only or primary material requiring transportation, such as in the construction of culverts and retaining walls or at the foundation phase of the building). Hence, concrete pumps are commonly used on building construction sites generally serviced by cranes, for one or more of the following reasons: (1) the crane is engaged in other lifting services, (2) a high placing output is required (typically for large pours), or (3) the location of the cast element is outside the reach of the crane. Concrete pumps are often also seen on sites where their ability to deliver the concrete while bypassing obstructions becomes useful, such as inside low-roofed spaces (e.g., tunnels), for renovation work on existing buildings, and on sites located such that access of any other transportation means is impossible (e.g., in old cities with narrow lanes). The effective pumping distance of common concrete pumps is 300 to 1000 ft horizontally and 100 to 300 ft vertically (although special pumps have moved concrete for much greater distances). The maximum theoretical output of commonly used pumps is 80 to 200 cu yd/hr, or even up to 300 cu yd/hr for the largest pumps available today, but these rates are rarely realized. Placing rates are determined in practice by the type and dimensions of the cast element, the size of the concrete placing crew, and the rate at which the concrete is fed into the intake hopper of the pump (an intake hopper can be seen in Figure 19.6b), the latter being dictated most commonly by gross truckmixer discharge cycle time. Effective outputs, in a properly organized placing operation and under normal conditions, are as follows:

- Common building elements of regular dimensions, 40 cu yd/hr
- Thick slabs and similar elements, 60 cu yd/hr
- Mass concreting of large elements (e.g., raft foundations), 80 cu yd/hr

19.3.2.2 Types and Configurations

The three main configurations of concrete pumping equipment are (1) a pump-and-boom combination, (2) a pump with a separate pipeline, and (3) a pump and pipeline with a separate, tower-mounted boom. The first of these is particularly efficient and cost-effective in saving labor and eliminating the need for pipelines to transport the concrete. The last of these, used mostly in high-rise construction, combines elements from the former two and is a less common configuration. The following description of these three configurations was adapted in part from Peurifoy et al. (2006).

19.3.2.2.1 Pump-and-Boom Combination

In this configuration (Figure 19.5), also termed a *boom pump*, the pump is mounted on a truck and equipped with a slewing boom to which a fixed-length delivery line is connected. The line is made of a

(a)

(b)

FIGURE 19.5 Pump and boom combination (boom pump): (a) arriving at site, with folded boom; (b) in operation, with extended boom.

steel pipe, commonly 5 in. in diameter. The free end of the line has a flexible rubber pipe (end hose), 9 to 12 ft long, connected to it. The end hose eases the task of the worker who holds it and can also be used to slightly extend the boom's reach.

Booms come in lengths of 60 to 210 ft, but the more commonly used booms are in the range of 80 to 140 ft. Hydraulically operated and articulated, booms in most truck-mounted pump models have four or five sections, but three sections for short booms and six sections for the longest ones are available, too. For a given boom length, a greater number of sections provides the boom with greater maneuverability, which may be an advantage in confined areas. Note that boom length is a nominal length and not the effective length of the boom. It indicates the maximum vertical reach of the boom, measured

from the ground, which includes the dead length from the ground to the first boom joint. Because this dead part is around 13 ft for most makes and models of truck-mounted pumps, the maximum horizontal reach of the boom, measured from the slewing axis of the boom, is always shorter by about 13 ft from the nominal boom length. Effective horizontal reach is even shorter, as loss of distance measured from the slewing axis to the front of the truck or to the truck side must be taken into account. Depending on truck make and size, the extended outriggers, by which the truck is stabilized while in operation, may also contribute to the shortening of the effective horizontal reach.

Truck-mounted pumps use one of two types of booms that differ from each other in their articulation mode. One type of boom extends convexly, but the other extends in a Z-like mode. Z-booms are particularly suitable for jobs with height restrictions (e.g., working under obstacles) and for confined spaces with low overhead, such as inside tunnels.

Because the reach of boom pumps is limited, these pumps use ready-mixed concrete, with the truck-mounted pump optimally positioned to enable maximum coverage of the concreting area for each concreting operation. If coverage from one location is not possible, the truck is relocated in the course of the operation. Relocation, however, interrupts work continuity and may cause delays, depending on the time it takes to fold the boom, retract the outriggers, move the truck, extend the outriggers, and unfold the boom to continue concrete placing. If the relocation was not planned, a line of waiting ready-mixed trucks may result as well.

Truck-mounted booms are available in two additional equipment configurations: as separate trailer placing booms and in combination with a trailer-type pump (see below). The trailer boom uses a two-wheel carriage with counterweights to help balance the extended boom. When combined with a trailer pump, the pump serves as a partial counterweight. In both configurations, the equipment is stabilized on outriggers when in operation. Booms in both cases are shorter than truck-mounted booms, and their maximum operation range is around 60 ft.

19.3.2.2.2 Pump with a Pipeline

In this configuration, also termed a *line pump*, the pipeline is a separate system that must be assembled and connected to the pump before pumping operations begin. The pipeline is laid from the location of the pump to the concrete casting area. The pump is located such that the ready-mixed concrete trucks have good access to it. In the case of on-site-mixed concrete, the pump would be placed with the hopper just under the discharge opening of the mixer. On spread-out projects, sizeable floor-area buildings, or high-rise projects comprised of more than one building, several pipelines can be stretched from one pump to various project zones, thus eliminating the need to relocate the pipeline with each change in casting location. A special pipeline gate is used to control which line is being used to any given pumping operation. Another option is to prepare several pipelines and relocate the pump according to the placement location. This latter option requires the use of truck-delivered ready-mixed concrete. In terms of its mobility, the pump is a stationary pump, trailer pump, or truck pump (not to be confused with the truck-mounted pump-and-boom combination). Figure 19.6 shows a truck pump being fed by truckmixers. Two mixers position themselves at the pump and feed it alternately such that concrete supply for the pump is continuous and a higher placing rate is achieved. Pipelines for concrete transportation use pipe diameters of 3 to 8 in. (with 5 and 6 in. being the most common sizes). The pipeline is assembled of straight and curved steel pipe sections connected to each other by quick couplings. Similar to the boom pump, here, too, the free end of the line has a 10- to 30-ft long flexible rubber pipe connected to it for better control of the concrete discharge location and for easier handling by the workers who have to direct the spreading of the concrete. To help with the difficult work of holding and moving the end of the concrete-filled pipe, a special lightweight distribution (or placing) boom can be used and crane-lifted for relocation as the concreting progresses.

19.3.2.2.3 Pump with a Pipeline and Tower-Mounted Boom

Given their limited boom length, boom pumps cannot provide solutions for high-rise buildings. Even the longest boom available, nominally 210 ft long, can practically place concrete in buildings no higher

(a)

(b)

FIGURE 19.6 Truck pump being fed by ready-mixed concrete trucks.

than 14 floors. The solution is, then, to use the basic pump-and-pipeline configuration, render it with climbing capability similar to that of the internal-climbing tower crane, and enhance horizontal distribution reach and convenience by use of a boom-pump-type hydraulic articulated placing boom (Figure 19.7). This configuration, used above in the selection example (19.2.2), is today the preferred solution for concrete placing in high-rise structures. Depending on the size of the floor in the constructed building,

FIGURE 19.7 Climbing placing booms.

two such systems may be used concurrently (with one or two pumps). In this case, either two booms are used (as seen in Figure 19.7) or one detachable boom, with a quick boom–mast connection, is transferred as required between the two climbing masts. The hollow-section or lattice-type climbing mast on which the boom is mounted and the pipeline running from the pump to the boom are located next to each other inside the building. However, an external climbing mast, similar to the mast of a top-slewing tower crane, can also be used.

19.3.3 Power Trowels

The final operations in the production of concrete elements that involve equipment are consolidating and finishing. Immediately following placement, concrete has to be consolidated by the use of vibrators (see Chapter 30). Finishing may actually be required only in the form-free faces of the cast element. Typical faces are the upper surfaces in floor slabs, where finishing to a smooth face—if required—is attained by the use of power trowels (Figure 19.8).

The main part of the power trowel is the rotating blade system, commonly termed *rotor* or *spider*. When the blades rotate at high speed, frictionally engaging the concrete surface, they improve the density of the upper concrete layer, seal plastic cracks, and polish the surface to obtain a smooth and hardened

(a)

(b)

(c)

FIGURE 19.8 Finishing of concrete floor by troweling: (a) walk-behind single trowel; (b) ride-on double trowel; (c) ride-on triple trowel.

concrete face. Maximum rotating speed is in the range of 90 to 180 rpm. Several steps are involved in troweling (the first step of which is termed *floating*), and with each step and successive troweling cycle the blades are slightly angled. Power trowels come in various rotor sizes (diameters). Large-size rotors are advantageous in large open areas, where high production rates can be realized; in tight spaces and mainly for finishing around various obstructions, small-size rotors or small troweling discs (see Figure 19.8a) must be used.

Powered by electric motors or by diesel or gasoline engines, trowels come in either a walk-behind or a ride-on configuration. In terms of number of rotors, the most common are single-rotor (Figure 19.8a) and double-rotor (Figure 19.8b) trowels, but triple-rotor trowels are also available (Figure 19.8c). Single-rotor trowels are of the walk-behind type, and the two others are of the ride-on type. Rotor diameter varies from 2 to 5 ft, and the number of blades per rotor varies from four to six.

Power trowels can be quite heavy, ranging from 100 to 300 lb for the single-rotor trowels and up to 500 to 3000 lb for double-rotor and triple-rotor trowels; the two latter owe their additional weight to the extra rotors, riding engine, and operator deck. To be crane-lifted around the jobsite and for loading and unloading, the lighter weight machines are fitted with a lifting hook, whereas the heavier machines have a robust lifting system. The latter are often moved around the workplace on transport dollies and transported between sites on trailers.

19.4 Cranes

Construction cranes are classified into two major families: tower cranes and mobile cranes. In some regions, including North America, the term *mobile cranes* is often used to refer to truck-mounted mobile cranes only, and track-mounted mobile cranes are considered a separate family, referred to as *crawler cranes*. This chapter adheres to the two-family classification. Some machine types are almost equally tower and mobile cranes. They are listed in this chapter under the family of their origin. Use of the word *family* in this chapter implies that a great many different equipment types and configurations fall under each one of the two terms *tower cranes* and *mobile cranes*. This chapter presents the main types and equipment in use today, with a focus on cranes that typically serve on building construction projects. The lack of universally accepted classification and taxonomy for cranes attests, too, to the great variety of both very different and quite similar crane types and models available. Because the various types of cranes can be confusing, an effort has been made in this chapter to be consistent in the use of these terms and to clarify such confusions.

19.4.1 Tower Cranes

19.4.1.1 Introduction

Tower cranes, essentially in the same configuration as we know them today, became visible in the late 1940s when they helped rebuild Europe after World War II. The tower crane was a small-footprint machine suitable for tight urban construction sites for both low-rise and high-rise structures, and it was powered electrically for noiseless operation. Over the years, the tower crane has seen enormous developments in terms of reach and lifting capacity, as well as deployment and operation convenience, suitability to a wide range of work assignments and site conditions, and responsiveness to the great variety of needs and preferences of construction firms and crane rental companies. Its operating and control systems have undergone major changes in parallel with the technological developments of our times, as has its safety features. Although the electrically powered tower crane is still the most common one, diesel-powered models are available and used as well, particularly in North America.

In high-rise construction, tower cranes essentially provide the only solution for lifting materials other than concrete, which can also be, and often is, pumped up. In many parts of the world, however, particularly in Europe, tower cranes are widely used for all kinds of building projects, urban and rural, as well as on infrastructure projects such as bridges, utilities, and landscaping. Lightweight, fast-erecting models are the machines of choice for the construction of low-rise residential and commercial structures, and even one-story houses, in France, Italy, Germany, and Switzerland, to name but a few. In recent years, these lighter models have begun to show a modest but growing and noticeable presence in North America as well, on a variety of projects having traditionally employed mobile cranes (Bishop, 2004; Shiffler, 2006a).

Tower crane “forests” have been conspicuous these past years in, among other places, the renewal of unified Berlin as Germany’s new capital in the late 1990s; the Chinese cities of Shanghai and Beijing, which is preparing for the 2008 Olympic Games; and the unprecedented surge of office, condominium, and hotel complexes in the United Arab Emirates in the mid 2000s. Yet, in the United States, as well, the increasing use of tower cranes has recently led to many cities being dubbed “Crane City”; for example, 300 tower cranes were estimated to have been working in Miami alone at one point in 2006 (Shiffler, 2006b).

Because tower cranes can be mounted on rails, a *traveling* tower crane had traditionally been a common way to obtain a larger work envelope and better site coverage whenever site conditions allowed installing a railway. This solution allowed saving at least one additional crane, as long as lifting requirements in terms of service time could be accommodated by one crane only. This, however, is not the situation for today’s typical construction sites. The competitive construction atmosphere and the high priority given to meeting tight deadlines practically dwarf the costs of additional cranes on site. Furthermore, with the increasing industrialization of construction sites, cranes are now busy providing a variety of lift services and in frequencies far surpassing yesterday’s requirements, thus demand on crane time has increased manifold. Consequently, cranes are often utilized to their full daytime capacity (and, in many instances, their nighttime capacity also) to meet all lifting requirements within their work envelope, but in many cases one crane cannot provide all of the lifting services required within its own reach within the time allotted. The result is a growing number of multi-crane sites, as well as a greater extent of shared work zones created by overlapping crane envelopes. This, in turn, has driven other developments in recent years; these developments, such as the increased use of *flat-top* tower cranes and the growing demand for advanced anticollision systems, are addressed later on in this chapter. The photograph appearing at the beginning of this chapter is an example of a multi-crane site (also see Figure 19.13).

19.4.1.2 Types and Configurations

The two main types of tower cranes are *top-slewing* and *bottom-slewing*. The major differences between these two types are reflected in erection and dismantling operations of the cranes and in their maximum height. Erection and dismantling of bottom-slewing cranes are relatively simple and rapid, earning these cranes the nicknames of *self-erecting* and *fast-erecting* (the latter, however, should not be confused with the same term often used by manufacturers to describe certain models of top-slewing cranes). This, however, comes at the expense of their limited height. Top-slewing cranes, on the other hand, take much longer to erect and dismantle when more complicated and costly operations are involved, but their height is practically unlimited. For these reasons, bottom-slewing tower cranes are suitable mainly for short-term service durations on low-rise projects, while top-slewing tower cranes are suitable primarily for mid-rise and high-rise projects requiring long service periods. A 6-month cut-off time is often cited in the industry when referring to the service durations of these two crane types, but this approximation should clearly be used, if at all, for general indication only.

19.4.1.3 Top-Slewing Tower Cranes

19.4.1.3.1 Structure and Configuration

The main parts of a typical top-slewing tower crane (Figure 19.9) are as follows:

- *Undercarriage*. These cranes are usually stationary, and crane stability is accomplished in one of two ways: (1) the mast is anchored directly into an engineered concrete foundation in a no-undercarriage configuration using fixing angles (see Figure 19.10), or (2) a base frame is ballasted by modular concrete blocks. In a traveling configuration, stability is attained by a concrete-block ballasted undercarriage mounted on rails. Rail-mounted undercarriages are sometimes placed on short rails for stationary, nontraveling use if the crane was originally procured in this configuration. Assisting in maintaining the stability in each of these configurations are the

counterweights installed on the counter-jib of the crane which is the most recognizable feature of top-slewing tower cranes. The undercarriage of a traveling crane also carries the traveling motors for the crane.

- *Mast.* Often termed *tower*, the mast is assembled of modular lattice-type sections (hence, the term *sectional tower crane*, which is also used for top-slewing cranes). When being erected, always by another piece of equipment, the crane will rise, section after section, to a certain initial height. Later on, it can climb itself with the addition of more sections. A hydraulically operated telescopic climbing frame (or climbing cage) is used to raise the upper part of the crane, thereby making room for the insertion of a new section, which is lifted and moved into place by the crane itself (Figure 19.11). In that regard, then, the crane has no height limit. Typical section lengths are 10 to 15 ft, but various other lengths exist, including exceptionally long sections (e.g., 40 ft) for city cranes, where speed of erection (determined, among other things, by the number of sections) is of the essence. (Note that the term *city crane* is not exclusive for tower cranes, as it is also used for certain types of mobile cranes.)

(a)

(b)

FIGURE 19.12 Top-slewing flat-top tower crane. Note the modern design operator cab with large window area.

- *Operator cab.* Located at the top of the mast, above the slewing ring, is the operator cab. It is either located co-centrally on the mast (as in Figure 19.9) or is attached to it on the side (as in Figure 19.12). Because tower cranes can rise to great heights, some crane models can optionally be equipped with a small elevator for the operator. In some European countries (e.g., Sweden and the Netherlands), such elevators, or similar means (e.g., a climbing operator cab), have recently become mandatory for cranes exceeding climbing heights of around 100 ft. (Note that the climbing height would be the full crane height in the case of a freestanding crane only; for taller cranes, braced to the constructed building, climbing begins at the top of the building or near its top, where a temporary bridge connects the building and the crane.) Today's operator cabs feature a comfortable and ergonomic work environment. Cabs are optionally fitted with air conditioning and similar other comforts to support a safer and more productive work environment; in particular, the window area has been increased (see Figure 19.12) to allow better vision of the site and greater control of rigging and hook movement.
- *Slewing ring.* This is the slewing (rotating) mechanism of the crane, located at the top of the mast right below the jib. It allows the entire upper part of the crane, which includes the jib and the operator cab, to slew while leaving the mast stationary. This is essentially what allows the mast to be braced to a permanent structure, thereby rising to any desirable height.
- *Jib.* There are several jib configurations for top-slewing tower cranes. The most common configuration is the horizontal *saddle jib*, also known as *hammerhead* (see Figure 19.9). It has a counter-jib, which carries, in addition to counterweights, the main motors, controls, and cable drum of

FIGURE 19.13 A cluster of flat-top tower cranes on a commercial building project in Budapest, Hungary. The photograph was taken in January 2007, when the site was inoperative, as is apparent from the weathervaning cranes. (Photograph courtesy Meir Simcha, Israel.)

the crane. The jib and the counter-jib are held by pendants (tie bars) connected to the top part of the crane, called the *cathead* or *A-frame*. A trolley moving along the jib (in a motion called *trolleying*) carries the lift cables and hook block. Similar to the mast, the lattice-type jib is modular, with several length options available within the maximum length prescribed for the given crane model. *Flat-top* cranes, also nicknamed *topless*, have a pendant-free, cantilever jib connected only to the mast (Figure 19.12). Sparing the use of a cathead, these cranes are particularly suitable for a shared-zone, multi-crane environment, where overlapping cranes must be set up to different heights (Figure 19.13). Because safety clearance must be maintained between the uppermost part of the lower crane and the jib-bottom of the higher crane, the entire length of the cathead frame, which could be as much as 40 ft, is gained in crane height when using flat-top cranes. This is also an advantage in situations with height restrictions, such as near airports. Flat-top cranes, however, have become very popular regardless of the above constraints due, for example, to their ease of set-up, and they now constitute a growing share of crane fleets in America. Another popular jib configuration is the *luffing jib* (Figure 19.14). Top-slewing cranes of this type, nicknamed *luffers*, do not use trolleys but rather change their operating radius by raising and lowering the jib. Many luffing-jib crane models feature a very short counter-jib; along with the luffing capability, it may be an advantage when the crane operates in proximity to other cranes or obstacles (such as nearby buildings). These cranes, therefore, are often seen in high-dense urban construction. A *moving-counterweight system* for luffing-jib cranes, first introduced several decades ago, appears to have regained some interest recently. This mechanism increases the distance between the counterweight and the mast as the jib is lowered and thereby causes less stress to be placed on the crane's structure. However, the moving-counterweight system has thus far had only limited use. (The two luffers in Figure 19.14 are fitted with moving counterweights.)

Top-slewing tower cranes are engineered to withstand high winds. This becomes particularly important at the heights these cranes often operate and is one of the advantages tower cranes have over mobile cranes. To ensure crane stability when the crane is unattended, tower cranes are left to slew freely with the wind, or to *weathervane* (see Figure 19.13).

FIGURE 19.14 Top-slewing luffing-jib tower cranes.

19.4.1.3.2 Transportation, Erection, and Dismantling

Top-slewing cranes, disassembled to their basic parts, are transported by any number of large trucks to the worksite. Preferably, the site would have adequate space to store these parts for later connection to larger assemblies using a smaller mobile crane than the one needed later to erect the tower crane. These larger assemblies would then be lifted up by a bigger mobile crane for assembly and erection of the tower crane (Figure 19.15a). When no such storage space is available, the tower crane may have to be erected directly off of the transporting trucks. For an urban site on a busy street, just-in-time delivery of crane parts may be required to minimize street closures. As mentioned above, a top-slewing tower crane requires another crane to erect it. The erecting crane is almost always a mobile crane, often two mobile cranes, unless the site is to have two or more overlapping tower cranes located close enough to each other such that the big cranes can be erected first and then used to erect some of the others. Dismantling the tower crane when its service is no longer needed is essentially the same process in reverse (Figure 19.15b), except that it may become more complicated because a building is now standing where there had been an empty space when the tower crane was originally erected. Quite often, a larger mobile crane will be required for dismantling than the one used for erection. These processes take from a few days up to a few weeks, depending on the size of the crane erected or dismantled, its location with regard to the constructed building, and accessibility of the erecting or dismantling crane. Bad weather, particularly winds, may be a delaying factor. Earthwork and foundation work, when required, add to setup time. Dismantling a crane climbing inside the building is a particularly complicated, long, and costly process. It is addressed separately in the next section.

19.4.1.3.3 Operation Modes

The common operation modes of top-slewing tower cranes are freestanding, externally braced, internal climbing, and traveling:

- *Freestanding.* If the model-specific maximum freestanding height of the crane, as specified by the manufacturer, satisfies the requirements of the project, this would be the most economic solution. Top-slewing cranes can now stand free of braces to heights in the range of 200 to 400 ft, much higher than before. One of several advantages of freestanding cranes is the freedom to place them virtually anywhere in the site.

FIGURE 19.15 Erecting and dismantling a top-slewing tower crane using a mobile crane: (a) erecting; (b) dismantling. Note the lane closure and interruption to traffic.

- *Externally braced.* If lifting service is required to heights greater than those possible with a free-standing crane, the crane must be braced to the constructed building, either as a full-height external climbing crane or as an internal climbing crane. To be braced externally to the building, the crane must be placed as close as possible to the façade of the building. Braces (or ties) to the building, commonly spaced 30 to 100 ft apart, are expensive additions to the cost of the crane. These braces are made of steel and are engineered to stabilize the crane and prevent mast buckling while absorbing horizontal motions of the mast. The cost of these braces sharply increases with the distance from the façade. One other issue associated with an external braced crane is completion of the façade after the crane has been dismantled.
- *Internal climbing.* The pros and cons of an internal vs. external climbing crane were mentioned earlier, as were those of climbing the crane in the elevator shaft or through openings in the slabs (see Section 19.2.2). A major issue with regard to an internal climbing crane is dismantling it at the top of the high-rise host building at the end of construction. In the case of more than one internal climbing crane servicing the building, the contractor should opt for taking down all cranes, but one, with each other. Sometimes, a high-rise building is serviced by two climbing cranes, one external and one internal, in which case the former may be able to dismantle the latter. In such cases, careful consideration of dismantling issues at the equipment-planning phase may affect crane location, lift capacity (i.e., greater than might otherwise be needed), and jib length (i.e., longer than might otherwise be needed). In most cases, if the use of an external tower crane for dismantling is not an option, then climbing cranes can be dismantled by one of two means: a mobile crane or a derrick. The mobile-crane option is faster and less complicated; however, it is an option only if two conditions are satisfied: (1) a mobile crane with the required vertical and horizontal reach is available, and (2) the vicinity of the building allows for setup of the mobile crane. It would be advantageous if the internal crane climbed near the façade of the host building

alongside which the dismantling mobile crane would be set up. If a mobile crane is not an option, which is always the case in the construction of ultra-high-rise buildings, then the tower crane to be dismantled can erect a derrick (Shapiro et al. 2000), which can then dismantle the tower crane and, in turn, be dismantled manually and taken down in small parts using the building elevator. Similarly, a custom-made hoisting apparatus may be used instead of a derrick. Another option, though seldom used, is the use of a helicopter.

- *Traveling.* As mentioned earlier, the crane in this operation mode is essentially freestanding. The railway can be either straight or curved. Preparatory earthwork is required, and the crane manufacturer typically specifies the maximum grade allowed (commonly 1%).

19.4.1.4 Bottom-Slewing Tower Cranes

19.4.1.4.1 Structure and Configuration

The main parts of a typical bottom-slewing tower crane (Figure 19.16 and Figure 19.17) include:

- *Undercarriage.* Unlike top-slewing cranes, which are often configured without an undercarriage, bottom-slewing cranes would always have an undercarriage to connect between the ground or any other supporting surface and the slewing crane. The undercarriage is commonly either stationary (Figures 19.16a and Figure 19.17b) or rail-mounted. Light models may have a wheeled undercarriage, but this is used only for infrequent crane relocations on the jobsite, without loads, and not for operation. In truck-mounted tower cranes (see below), the truck replaces the conventional undercarriage. Another configuration, seen mainly in Europe, is that of a crawler undercarriage (Figure 19.16b). Whenever it is not in motion, the crane is stabilized by outriggers.
- *Slewing ring.* The slewing ring of the top-slewing crane is located near the top of the crane, but the slewing ring of a bottom-slewing crane is located near its base, such that practically the entire crane—slewing platform, mast, and jib—can slew. For this reason, the mast cannot be braced to the building for increased stability, and its height is limited.
- *Slewing platform.* The slewing platform carries, in addition to the mast, the entire ballast of the crane, as well as the motors. To balance the crane, the ballast blocks are located at the rear of the platform, always opposite the jib. To be most effective, the greatest possible distance between the ballast and the mast would be desired. On the other hand, the smallest possible projection of the rear end of the platform from the footprint of the crane (as determined by the undercarriage) is desired to allow crane setup in close proximity to the building and for increased safety. Newer models, therefore, have a compact platform, compensated for by a high stack of ballasting concrete blocks.
- *Mast.* Earning the bottom-slewing tower crane the name *telescopic tower crane* (to distinguish from the sectional top-slewing crane), the mast of this crane is made of two to three telescoping parts. This type of structure is in line with the limited height of the crane and, even more so, with its rapid self-erecting concept. The operator cab is traditionally located at the top of the mast, or the crane can be operated from a control post at the lower part of the mast. Many new models now offer a climbing cab that can move along the mast for optimal view (Figure 19.17b). Wireless radio remote control of these cranes is now offered on most models. Masts are either lattice (Figure 19.16) or hollow section (Figure 19.17). Hollow-section masts used to be common only on smaller models but are increasingly being seen on larger models, as well. In smaller models, this hollow-section mast is often foldable instead of telescopic.
- *Jib.* The lattice-type jib is similar to the main jib (i.e., no counter-jib) and trolley system of the top-slewing crane; however, it is foldable for fast erection and dismantling and, in many models for a shorter jib work option. Some models feature a telescoping jib. Unlike top-slewing cranes, where the horizontal jib and the luffing jib are two different crane configurations altogether, the jib of the common bottom-slewing crane can usually be raised, though not in a sharp angle (commonly up to 30°), while maintaining trolley movement. This grants the initially height-limited crane an additional lifting height. Some models have an articulated jib, in which the part closer to the mast is horizontal and the outer part can be angled upward.

FIGURE 19.18 Bottom-slewing tower crane in towing position. Note the concrete ballast blocks, at the right of the picture, to be carried by the towing truck.

19.4.1.4.2 Transportation, Erection, and Dismantling

Convenient transport, erection, and dismantling are the main features of these cranes. Towable by a truck or a semitrailer for transportation between jobsites, they are usually mounted on a designated wheeled undercarriage in a fully folded position (Figure 19.18). For relocation on the jobsite, partial folding suffices. Erection and dismantling are performed by the crane itself, using its own motors. Light models may be erected and dismantled within an hour, but heavier models may take up to one day.

19.4.1.4.3 Operation Modes

Operation modes of bottom-slewing tower cranes, as dictated by the means of their mobility, are stationary, rail-mounted, crawler-mounted, and truck-mounted:

- *Stationary.* The crane is stabilized by outriggers. It is folded partially or fully for relocation on the site, but light models can be towed in an upright position. Some models are self-propelled (for relocation only); moving on wheels, they require a hardened surface, usually with a maximum ground gradient as specified by the manufacturer. By no means is the crane allowed to move with a load.
- *Rail-mounted.* Same as with top-slewing cranes, this type of crane can travel with its load, assuming a work envelope whose size is limited only by the length of the railway.
- *Crawler-mounted.* This mode is suitable for operation in rough and sloping terrains. Bottom-slewing cranes of this type can accommodate both longitudinal and transverse gradients and are commonly equipped with a balancing mechanism. For lifted loads or ground slopes exceeding certain specified values, the crane must work on its outriggers.
- *Truck-mounted.* This is an old concept that has seen a renaissance in recent years. Essentially a hybrid configuration combining a mobile crane and a tower crane, it combines some key features of these two crane types—mainly, the mobility of the truck crane with the height and reach of the tower crane where lifting requirements do not call for a larger crane.

19.4.1.5 Technical Data

The major technical data relevant to selection of tower cranes, top-slewing and bottom-slewing alike, are (1) jib length, (2) lifting capacity, and (3) lifting height. These data determine the work options and ranges of a crane, as well as the crane's suitability for a given project or for a specific type of projects. Many other pertinent data, such as footprint dimensions, mast cross-section, motors power, and speeds,

are decisively dictated by these three parameters. Tower cranes are manufactured in a great variety of models in terms of jib length, lifting capacity, and lifting height, to cater for the great variety of building dimensions and construction methods. The broad range of tower cranes offered on the market can be classified into four classes by their size and designation:

- *Light cranes* are designated for maintenance and renovation works in buildings up to about four stories and for the construction of one- to two-story structures. These kinds of projects are characterized by material batches of 1000- to 2000-lb maximum weight and a relatively short duration of the crane on the jobsite; therefore, this class of cranes is manufactured as bottom-slewing cranes only.
- *Medium cranes* are designated for the construction of cast-in-place concrete structures using conventional or industrialized methods (e.g., using large form panels), with the possible combining of certain precast elements (e.g., flights of stairs). This category of structures is characterized by material batches of 2000- to 5000-lb maximum weight, varying crane service durations on-site (depending mostly on the height of the constructed building), and a broad range of building heights. Cranes in this class are manufactured both as bottom-slewing cranes, suitable mainly for structures up to eight stories high, and as top-slewing cranes, suitable mainly for structures six stories or taller. Because this kind of building constitutes the majority of buildings, these are also the most widely used tower cranes.
- *Heavy cranes* are designated for the construction of structures using precast methods or other methods that combine heavy elements. The central attribute of these structures is building components weighing 5000 to 13,000 lb. Cranes in this class are mostly top-slewing cranes; the small number of bottom-slewing models in this class fall in the lower part of this weight range.
- *Special-application cranes* are designated for the construction of unusual structures in terms of their size, weight of elements, or site conditions (e.g., nuclear plants, dams). These cranes, exceptionally large in jib length, lifting capacity, or lifting height, are always manufactured as top-slewing cranes.

Table 19.4 presents typical technical data for tower cranes by the classes listed above. Following are some explanations with regard to the headings in Table 19.4, as well as several other technical features of tower cranes.

Jib length is the maximum working radius, measured from the centerline of the mast to the centerline of the trolley at the jib end. It is the maximum length offered with any specific crane model; however, as mentioned above, most crane models can be configured with shorter jibs. The *lifting capacity* of the crane changes with the work (or lifting) radius, as determined by the distance of the trolley from the mast. The crane can lift its heaviest load (*maximum lifting capacity*) at a certain model-specific radius (often termed *minimum radius*), after which lifting capacity decreases gradually until it reaches its minimum at the end of the jib (*jib-end lifting capacity* in Table 19.4 but often referred to as *maximum lifting capacity at maximum radius* or *tip capacity*, for short). No heavier loads can be lifted at radii smaller than that minimum radius. Maximum lifting capacity at the end of the jib is governed by the structure and overall stability of the crane. Maximum lifting capacity at *minimum* radius, however, is additionally governed by the strength of the lifting cables. Most tower cranes can use either a single cable (*two-part line*) or a double cable (*four-part line*). With a double cable, maximum lifting capacity at minimum radius is doubled (though at the expense of a 50% reduction in hoisting speed). As for maximum lifting capacity at maximum radius, not only is it unchanged with a double cable but it also drops somewhat compared to a single cable, as the extra cable weight reduces the net lifting capacity.

Tower cranes are occasionally denoted by their *lifting moment*, commonly computed by multiplying the maximum jib length by the end-of-jib maximum lifting capacity. Note, though, that although it provides some indication of the size of the crane, this parameter discloses no information with regard to jib length or lifting capacity. *Lifting height* of a crane denotes the maximum height to which the lifting hook can be raised, which is slightly lower than the bottom of the jib. The maximum allowable height of a building to be serviced by a crane is at least 20 ft lower than the lifting height of the crane.

TABLE 19.4 Technical Data for Tower Cranes

Properties	Class and Crane Type					
	Light Cranes	Medium Cranes		Heavy Cranes		Special Cranes ^b
	Bottom-Slewing	Bottom-Slewing	Top-Slewing	Bottom-Slewing	Top-Slewing	Top-Slewing
Jib length (ft)	50–80	80–150	100–150	150–180	150–250	250–330
Jib-end lifting capacity (lb)	1000–2000	2000–5000	2000–5000	4000–7000	4000–13,000	7000–100,000
Maximum lifting capacity (lb)	2000–5000	5000–18,000	5000–20,000	10,000–20,000	15,000–80,000	50,000–350,000
Lifting moment (ton-ft)	35–80	80–250	140–300	300–600	350–1200	1000–15,000
Maximum freestanding height ^a (ft)	50–70	70–110	110–200	100–130	150–250	200–450

^a For rail-mounted traveling cranes: 100 ft for bottom-slewing, 230 ft for top-slewing, excluding special cranes.

^b Data provided do not include cranes at the far extreme of this range. The largest tower crane model known to have ever been manufactured, the K-10,000, can lift 220,000 lb at the end of its 330-ft long jib (i.e., 36,000 ton-ft lifting moment). About one dozen of these cranes have been manufactured (by the Danish manufacturer Krøll) and are known to be still operating at this time.

Crane cycle time and work output are largely determined by the speed of the crane's various motions, as has already been demonstrated above (see Section 19.2.2.2). Common speeds are as follows:

Hoisting (vertical), 150 to 500 ft/min

Trolleying (radial), 100 to 350 ft/min for top-slewing, 60–200 ft/min for bottom-slewing

Slewing (circular), 0.6 to 1.0 rpm (0.8 for most makes and models) for top-slewing, 0.8 rpm for bottom-slewing

Traveling (horizontal), 65 to 100 ft/min

When estimating cycle-time durations, due attention should be given to the normal mode of operation in which the crane operator exercises two, sometimes even three, motions simultaneously. Additionally, loading and unloading times have to be considered; in low-rise building, they constitute the major part of the cycle time. Unloading can be particularly long when accurate placing of elements such as flying forms or precast panels is required.

19.4.2 Mobile Cranes

19.4.2.1 Introduction

Unlike the tower crane, which essentially is a stationary machine even when it has acquired some mobility capabilities, the mobile crane is what its name implies—a self-propelled mobile machine, capable of moving freely about the jobsite and between jobsites, as well. Contrary to the silhouette of the tower crane as a vertical mast with a horizontal jib at its top, the jib of the mobile crane—termed *boom*—is inclined and connected directly to the carriage of the machine. The variety of tower crane types, as presented above, may appear to be wide, but the mobile crane itself features a great many more types and models, and it can range in size from small machines that fit in the wagon of a pickup truck to gigantic machines that dwarf almost any other construction equipment.

Mobile cranes owe their extensive use in North America to the ambitious heavy civil and infrastructure projects this country has launched since the early 20th century. In part, this is also due to the developed agricultural machinery industry, thought to be the motivated power behind the birth of heavy construction equipment in the United States. Among other things, this has contributed to the great versatility of

FIGURE 19.19 Mobile cranes on a mid-rise concrete building construction project.

mobile cranes, which until merely a decade ago were equally associated with non-building operations, such as excavation, pile driving, and demolition, and with building construction per se. Even today, these machines find their main use in a great variety of civil engineering projects other than building construction. Some mobile crane types, however, show great presence on building construction sites, whether for short-term tasks or throughout most of construction (Figure 19.19). If for no other use, they are the machines that set up the tower cranes at the onset of construction and dismantle them at the conclusion of their service on site. This is a classic demonstration of the mobile crane's main features: its capacity to handle heavy loads and its rapid deployment. A relatively small mobile crane has a lifting capacity equal to that of a heavy tower crane. The high-end mobile cranes can lift hundreds of tons.

While the major types of mobile cranes are mentioned in what follows, the focus in this chapter is on the types used in building construction. It should be stressed that concrete building construction involves a great extent of *duty-cycle* work, namely, work in which the crane is engaged in repetitive lifts of relatively short cycle time. Handling a bucket for concrete placing is a typical example of such work. While tower cranes inherently are suitable for duty-cycle work, mobile cranes are not so. Because loads involved in cast-in-place concrete building construction are relatively low, mobile cranes—of various types—that are fitted for duty-cycle work are commonly of the small- to mid-size models.

19.4.2.2 Types and Configurations

Mobile cranes are characterized and distinguished from each other mainly by two parameters: their undercarriage (or carrier) and their boom. The two types of undercarriage are *wheeled* and *crawler*, and the two types of boom are *lattice* and *telescopic*. Combinations of these two parameters yield four different machine types; however, other parameters, such as mobility, accommodation of varying ground surfaces, and rigging mechanisms, add more types to the large class of mobile cranes. Common to all of these types is their suitability to meet lifting requirements in which they have an advantage over tower cranes: handling of heavy loads, short-term lifting services, and various transportation works requiring frequent relocation of the crane on the jobsite. These characterize the kinds of construction projects where the capabilities of mobile cranes are maximized.

19.4.2.2.1 Boom Configurations

The *lattice boom* is made of lattice-type steel sections, similar to the mast sections of tower cranes. The number of sections varies according to the desirable boom length. There are always two pyramid-shaped

end sections. The length of the boom is fixed and cannot be changed in the course of work, unless the boom is lowered and sections are added or taken out, thus work height and radius change due to changes in the inclination angle of the boom. An auxiliary boom (boom extension), known as a *fly jib*, can be fitted angularly to the end of the main boom, giving the crane farther reach for better building coverage (see Figure 19.19). In larger crane models, this boom extension is often longer than the main boom of the crane. The *telescopic boom* is made of telescoping sections. It is operated hydraulically, allowing boom length and inclination to change in the course of work. A short, straight, lattice-type extension boom can be connected to the end of the telescopic boom. When not in use, this extension boom is stowed next to the telescopic boom such that its connection is convenient and rapid (see Figure 19.21). Additionally, a short auxiliary boom, commonly of the hollow-section type, can be fitted to the end of the extension boom. A lattice-type fly jib, same as with the lattice main boom mentioned above, is also very common (see Figure 19.15a).

The main advantage of the lattice boom is its simple structure and, consequently, its lower cost. It is also the preferable boom for cranes with exceptionally high loading capacities. The telescopic boom, on the other hand, offers two important advantages that account for the growing popularity of this type of boom: (1) more efficient crane use due to the continuous adjustment of boom length in the course of work, and (2) much faster crane deployment, as compared to complicated rigging and unrigging of the lattice boom, which often requires the assistance of other lifting means and separate transportation.

The lifting capacity of the crane, whether equipped with a lattice or telescopic boom, changes with the boom's length and inclination angle. The minimum working radius is attained at the shortest boom length and the most upright possible boom position (i.e., minimum inclination angle when measured from the vertical). Although varying with crane configuration and model, this minimum radius is commonly taken as 10 ft nominally. This is important because mobile cranes are often denoted by their maximum lifting capacity at this nominal minimum working radius, although no standard universal rating system exists. For example, a 100-ton crane is likely to have a maximum lifting capacity of 100 tons, effective at a 10-ft radius, which corresponds to a lifting moment of 1000 ton-ft.

19.4.2.2.2 *Truck Cranes*

Truck cranes are suitable mainly for short-term lifting assignments; this is not the kind of a crane seen working for extended durations on construction sites. The superstructure of this crane, which includes the boom (lattice or telescopic), engine, counterweight, and operator cab, is mounted on a specialized carrier truck. Connecting the two is a slewing ring ("turntable") allowing a full 360° rotation. The crane travels the public road system (with a retracted telescopic boom or partial lattice boom) essentially like any other truck but can also travel on rough roads. To utilize its maximum lifting capacity, the crane must be leveled and stabilized on its outriggers while in operation; it can operate while on its wheels to only partial capacity. Because of the high loads these machines transfer to the ground through the outriggers, mats of various sizes must be used to spread the load, as depends on the soil-bearing capacity. Together with the extended outriggers, these mats increase the overall width of the vehicle, which should be taken into account when planning the lift and the crane's exact location.

Lattice-boom truck cranes are gradually making room for telescopic-boom truck cranes, given the greater flexibility of the latter in moving between jobsites. This trend has been observed, initially in Europe and in recent years in North America, with regard to truck cranes in general, due to the growing popularity of *all-terrain cranes* (see below). However, truck cranes—both lattice-boom and telescopic-boom—appear to be maintaining their standing as a viable option when no particularly rough-terrain site conditions have to be accommodated, due mainly to their lower cost compared to all-terrain cranes.

A different style of truck crane has recently appeared on the market. Nicknamed the *city crane* and featuring a compact design, lower boom mounting, and a single dual-purpose (truck and crane) operator cab, it is designated mainly for urban work and travel. Often confused with truck cranes are **truck-mounted cranes**. The main difference is the carrier vehicle—a standard-type truck in the truck-mounted crane, a specialized truck in the truck crane; truck cranes also have, in general, higher lifting capacity. Truck cranes are manufactured as an integral (though often modular) unit by the same manufacturer, but different manufacturers supply the truck and the crane components for truck-mounted cranes.

FIGURE 19.20 Crawler crane.

19.4.2.2.3 Crawler Cranes

The revolving superstructure of the crawler crane is similar to the superstructure of the truck crane but is mounted on a crawler undercarriage. This change from the truck crane has several implications, in that the crawler crane has better maneuverability and offers outrigger-free work with rapid relocation within the jobsite but requires longer transfers between sites, including loading it on a haul truck. Given these qualities, crawler cranes (Figure 19.20) are particularly suitable for jobs with difficult ground conditions and for projects requiring frequent crane movement. Due to the usually long on-site service, the importance of convenient transfer between sites is reduced, and the majority of crawler cranes have traditionally been equipped with lattice booms. For some uses, however, a crawler crane with a telescopic boom might appear an appropriate option. For this reason, in addition to the growing attractiveness of telescopic booms in general, smaller crawler telescopic-boom crane models have recently begun appearing on the market. One application of such a crane would be on urban projects in areas where contact pressure with the street surface is restricted due to underground facilities. Wheeled or outriggered undercarriages may not be suitable under these conditions, but a rubber crawler telescopic-boom crane that can travel on pavement would be. A crawler undercarriage also serves as a platform for what is known as the *American-type tower crane*, which is a crawler crane rigged with a tower attachment made up of a vertical lattice boom fitted at its top with a luffing boom. In essence, this is a more robust version of the crawler-mounted bottom-slewing crane, exclusive of trolleying capability.

19.4.2.2.4 Rough-Terrain Cranes

Arguably the most visible mobile crane on a great variety of construction sites the world over, the smaller models of rough-terrain cranes are often used as high-mobility auxiliary equipment on building sites that employ tower cranes as the central lifting services providers. As implied by its name, the crane is designated mainly for lifting works on sites with rough terrain conditions and frequent relocation on the jobsite. The high-ground-clearance, wheeled undercarriage of this crane (Figure 19.21) has two closely spaced axles and large wheels. With a retracted boom, the crane has the ability to move on steep slopes; some models can manage grades up to 70% (35°). At the same time, the crane can travel the public road system, although commonly in speeds not exceeding 25 mph and in low driving comfort, which is why it is often hauled on a low-bed truck between jobsites. The operator cab is either a fixed part of the undercarriage or is part of the superstructure and rotates with the slewing of the boom (see Figure 19.21a). Usually equipped with a telescopic boom, it can also use a

(a)

(b)

FIGURE 19.21 Rough-terrain crane: (a) in operation; (b) in stowed position.

quick-fitting, lattice-type extension boom to which an additional auxiliary boom can be added. Extension and auxiliary booms, stowed alongside the main boom, can be seen in Figure 19.21b, and the auxiliary boom is shown in Figure 19.21a. The rough-terrain crane can be utilized to its full lifting capacity when operating on its outriggers; however, because it is designated to provide lifting services requiring constant movement on the jobsite, it can carry loads while on its wheels and in motion, though to partial capacity only, depending on ground conditions, speed, working radius, and type of tires. In any case, moving with a load can be carried out only when the boom is oriented along the longitudinal axis of the crane. Model-specific allowable load ratings under various conditions are provided by crane manufacturers.

FIGURE 19.22 All-terrain crane.

19.4.2.2.5 All-Terrain Cranes

Relatively new to North America, all-terrain cranes (Figure 19.22) combine the best of truck cranes and rough-terrain cranes. The number of models offered by manufacturers is constantly growing in response to the increasing demand for these telescopic-boom cranes worldwide. These cranes cannot accommodate ground slopes as steep as those manageable by rough-terrain cranes but their maneuverability is better than that of truck cranes. At the same time, they can travel public roads at much higher speeds and with greater comfort compared to rough-terrain cranes. Boom configuration and extension options are similar to those of rough-terrain cranes. Tilting operator cabs have become standard (Figure 19.23); they improve

FIGURE 19.23 Tilting operator cab on an all-terrain crane superstructure.

operator view and increase operation efficiency while preventing neck strain. In terms of technology and features, all-terrain cranes are perhaps the most advanced and sophisticated mobile cranes offered today, as reflected in their high price and the high lifting cost per unit tonnage for these cranes.

19.4.2.2.6 Specialized Cranes

This class of mobile cranes includes a variety of enhanced lifting capacity machines only seldom used on concrete building construction sites. They usually feature a lattice boom stabilized by a rear mast and mounted on specialized trucks or crawlers, often with various other counterweight-carrying assemblies. These machines are perhaps the largest and most powerful of any construction equipment manufactured; their maximum lifting capacity now approaches 2000 tons. Accordingly, their transportation, setup, and dismantling are exceptionally complicated.

19.4.2.3 Technical Data

Table 19.5 presents typical technical data for mobile cranes.

19.4.3 Cranes in the Electronic Age

Developments in computerization and communication have not overlooked the world of construction equipment. Today's novel crane models are electronically loaded with regard to their drives, controls, monitoring, and communication. Whether standard or optional, various advanced-technology features are aimed, among other things, at enhancing crane work productivity and safety. A multitude of auxiliary systems is offered by both crane manufacturers and the crane peripheral industry to support crane selection and operation, as well as equipment maintenance and fleet management. Many of the systems are integral part of new cranes only, while others can be fitted on used cranes as well, thereby upgrading their operation. Only three types of developments are mentioned here as examples of the abundance of systems available on the market:

- *Selection software.* These advanced graphics software packages are helpful in dealing with the “hard” technical and engineering aspects of crane selection and location, as well as lift planning. As a minimum, they serve as structured checklists of all site and machine parameters that have to be considered; however, their main asset lies in their facility to check a great number of alternatives instantly. Some of the packages offer crane databases containing built-in dimensions and capacities of common equipment models by various manufacturers. Most packages available on the market handle mobile cranes only, but some of them accommodate tower cranes as well (Meehan, 2005).
- *Camera systems.* Lifting operations involving concealment of the work zone or travel path from the operator's eyes, often termed *blind lifts*, are very common in crane work, for both tower and mobile cranes. The use of signalers is the common solution the world over; no safe blind lift can be performed without a signaler—or several of them—using hand signs or radio communication, or both. In many countries, the presence of at least one signaler on a site using a crane is mandatory by law. Many crane-related accidents have been attributed, wholly or partly, to faulty signaling for various reasons (such as high worker turnover, inadequate signaler training, and language barriers, to name but a few). Crane-mounted video camera systems (Figure 19.24), available for both tower and mobile cranes, help overcome most of the safety problems associated with blind lifts. They also have the potential to increase crane work productivity due to speedier work and shorter cycle times. The camera, installed on the trolley of the tower crane or the boom end of the mobile crane, is permanently directed downward at the work scene, with the lifting hook constantly located at the center of the image. The video image is processed and the picture of the load and its immediate surrounds is transmitted, via wireless communication, to a monitor located in the operator cab (Howes, 2005; Shapira et al., 2008).
- *Anticollision systems.* Combining hardware and software, these systems are devised to prevent collisions of tower cranes operating in shared zones, a common safety hazard on construction sites employing more than one tower crane. The systems use wireless and various other advanced

TABLE 19.5 Technical Data of Mobile Cranes

technologies to monitor the movements of the crane in real time; warnings are followed by automatically slowing down the crane motion and, eventually, by completely stopping the crane. Most anticollision systems are designed to prevent collisions with adjacent buildings and other obstacles, such as power lines, as well as slewing and trolleying over areas defined as prohibited zones, such as busy streets and public buildings. These added features make the systems useful on single-crane sites, as well. Due to the fairly high price of these systems and the tendency of construction firms to adhere to old, traditional solutions, the use of these system so far has been limited primarily to multi-crane projects. Today, though, they have come to be appreciated by a growing number of construction firms that are opting to use them on sites with a small number of cranes, as well.

19.5 Truck Loaders

The truck loader, also known as a *crane truck* or *boom truck*, is a payload truck fitted with a crane, thus making up a combined hauling and loading self-contained unit. A subclass of the telescopic-boom truck crane and often confused with the similar truck-mounted crane (see Section 19.4.2.2.2), this type of equipment is listed here separately because the concept is completely different. Whereas the truck crane and truck-mounted crane are first and foremost cranes mounted on a wheeled carrier for mobility, the truck loader is initially a hauling truck that is then equipped with a loading crane (hence, the term *loader crane* is also used for this equipment). Several differences between truck loaders and truck cranes or truck-mounted cranes can be identified:

- The truck loader uses a standard commercial truck chassis, while the truck crane uses a specialized carrier (although the truck-mounted crane also uses a standard chassis).
- The truck loader transports its own payload, although it often provides lifting services other than to do with its hauled loads. Truck cranes and truck-mounted cranes have no cargo-hauling capacity whatsoever.
- Truck loaders are smaller than truck cranes, and their lifting capacity is reduced compared to that of truck cranes.
- The truck crane often requires special permits and provisions to travel public roads and city streets, but the truck loader is a regular vehicle in that regard.
- Truck cranes are commonly owned by crane rental companies (but sometimes by sufficiently large construction companies), whereas the truck loader is usually owned by its operator.
- Truck cranes may stay on-site for long hours or days, but truck loaders commonly provide short-term services, often staying on-site less than one hour and visiting several sites on the same day (hence, the terms *taxi crane* and *service crane* are often used for this equipment).

Truck loaders are characterized mainly by the type of boom: a *knuckle-boom* truck loader has an articulated folding boom; a *stiff-boom* truck loader has a straight telescopic boom. The end section of the knuckle boom can also extend telescopically. Some booms feature a basic folding configuration with a stiff-boom end section.

The use of knuckle-boom truck loaders (Figure 19.25) is more widespread, and the number of models of this type offered on the market is considerably greater than that of straight-boom truck loaders. The booms of both types are commonly mounted directly behind the truck cab, facing rearward. This way, most of the truck bed is left free for cargo. A newer and less common configuration is of a rear-mounted boom, leaving smaller space for cargo but allowing for increased lifting capacity, as the boom is supported directly on the rear axles. Featuring a slewing upper-structure resembling that of the truck-mounted crane, these rear-mounted boom models allow operation from a seat, often enclosed in a cab. This is in contrast to the regular truck loaders, which are operated from a stand-up station (most models have two such stations, one on each side of the truck, or even more). This makes a big difference in terms of operation convenience, particularly in bad weather. Typical dimensions and capacities of truck loaders are given in Table 19.6.

FIGURE 19.25 Knuckle-boom truck loader in form-assembly work.

TABLE 19.6 Technical Data of Truck Loaders

Properties	Boom Type			
	Articulated Boom		Straight Boom	
	Common Range	Largest Machines	Common Range	Largest Machines
Lifting moment (ton-ft)	10–200	500	5–70	200
Maximum lifting capacity (lb)	2000–40,000	60,000	2000–20,000	40,000
Maximum radius (horizontal reach) ^a (ft)	20–80	130	10–40	80
Maximum lifting capacity at maximum radius (lb)	1000–5000	20,000	500–3000	10,000

^a Maximum vertical reach above ground is 3 to 6 ft more than maximum horizontal reach in the smaller model and 10 to 14 ft more in the larger models. Most truck-loader models feature below-ground reach, as well.

On the construction site, truck loaders offer advantages in both of their service modes. As independent hauling and loading equipment, they can save crane time by self-unloading their cargo (or picking up cargo from the site), as well as by lifting it directly to where it is needed, within the reach limit of the boom. They also have an advantage in being able to drop off or pick up cargo outside the work envelope of cranes at the site. Their hourly operation costs are lower than those of on-site trucks or rough-terrain cranes which is why, on some low- to mid-rise building projects as well as many non-building project types, there is a preference to use truck loaders quite frequently on an on-demand basis, rather than maintaining a resident crane on-site (see Figure 19.25).

FIGURE 19.26 Truck-mounted telescopic belt conveyor.

19.6 Belt Conveyors

Placing concrete by belt conveyors had been popular in North America, particularly for high-volume, fast-rate pours. Belt conveyors, available in a variety of configurations, are still used but not as commonly as before, having been replaced gradually by the more popular concrete pump. One advantage of belt conveyors over concrete pumps is their ability to transport other bulk materials, such as sand and gravel, as well as concrete. Another advantage is their ability to transport coarse aggregate concrete and dry concretes, which a concrete pump cannot do.

Belt conveyors used in the mining industry, quarries, and central mixing plants are stationary and can be quite long; however, the use of belt conveyors for construction requires high mobility and, consequently, relatively short conveyors. Belt conveyors for placing concrete are either stand-alone portable units or equipment fitted onto a host carrier, such as a truck, mobile crane, or truckmixer. To be fed by a truckmixer, the feeder hopper of the conveyor must be adequately low. The concrete is then conveyed upward, either directly to its discharge location or to additional conveyor segments moving it further horizontally, upward, or downward to the final placement location.

A popular configuration is that of the truck-mounted telescopic conveyor (Figure 19.26), resembling a truck-mounted boom pump. The boom can rotate a full circle, and the truck can set up and operate under heights as low as 15 ft. Typical dimensions and capacities of this equipment are as follows:

- Maximum horizontal reach, 50 to 125 ft
- Maximum upward angle, 30°
- Maximum horizontal reach at maximum upward angle, 40 to 110 ft
- Maximum discharge height above ground, 30 to 70 ft
- Maximum downward angle, -10° to -15°
- Maximum discharge height below ground, 5 to 25 ft

A different belt-conveyor type, used mainly on civil-engineering projects requiring long conveying distances, is the series conveyor. It is composed of modular segments and typically conveys concrete up to 600 ft away from the feeding truckmixer.

19.7 Material Handlers

Telescopic-boom material handlers, known as *telehandlers*, first appeared in the early 1980s and have grown constantly in popularity ever since. They are today's classic multi-purpose equipment on construction sites, due to their high mobility, versatility, and reach (both horizontal and vertical). The

(a)

(b)

FIGURE 19.27 Telehandlers: (a) as a forklift, stowed boom; (b) in concrete placing.

increased popularity of telehandlers can be attributed to their usefulness on industrial, agricultural, and construction sites alike, as well as to the increasing use of materials packed and delivered to the site for forklifting on pallets. A variety of front-end attachments can easily and quickly be interchanged, so telehandlers can be configured not only as forklifts but also as cranes, front loaders, concrete buckets, access platforms, and more. Telehandlers (Figure 19.27) are wheel based and can commonly travel at up to 25 mph. They feature good site maneuverability on various ground surfaces due to their two axles and high ground clearance, as well as their advanced drive, steering, and lateral-balancing capabilities. To fully utilize their lifting capacity with an extended boom, most telehandler models operate on outriggers (often termed *stabilizers* with this equipment). Some telehandler models have performance enhancements such as a fully rotating upper structure (*slewing handlers*), forward horizontal boom motion at any height from the chassis, elevating forks, carriage side shift, and a tilting operator cab. The rapidly evolving telehandler market offers a great many models with ever-growing reach and capacity

ranges. The telehandlers of the 1980s were able to serve up to three-story buildings, but telehandlers today can reach up to the ninth story. Some of the largest machines available today are not much different in size and capacity from small rough-terrain cranes. Typical dimensions and capacities are as follows:

- Maximum load capacity, 6000 to 20,000 lb
- Maximum vertical reach, 20 to 80 ft
- Maximum load capacity at maximum vertical reach, 2000 to 10,000 lb
- Maximum horizontal reach, 10 to 60 ft
- Maximum load capacity at maximum horizontal reach, 1000 to 4000 lb

19.8 Hoists and Lifts

The three main types of personnel lifts used on building construction sites are the mast-climbing passenger hoist, scissor lift, and aerial work platform. **Mast-climbing passenger hoists**, also used as material hoists, are the only personnel-movement solution for high-rise construction. No high-rise building is constructed anywhere in the world without using this type of hoist; on some buildings, several units are used. As construction progresses and the building rises, the constructor has to decide when to install the hoist; until it is installed, workers and other personnel must use the stairs (permanent or temporary). Typically, buildings ten stories and higher use passenger hoists; on taller buildings, the hoist may be installed early on, before the building reaches that height. When construction has reached the top and the permanent lifts have been installed, the hoist can be dismantled, although it often stays in service almost to the end of construction. The mast is erected outside the building next to the façade to which it is braced. After it is dismantled, some finishing work may have to be done where the ties were anchored to the building.

The climbing passenger hoist is a heavy-duty, old-concept machine that excels in safe performance. On the site, it is probably the first machine to begin running in the morning and the last one to shut down at the end of the workday; in between, it hardly ever stops. There are single-car and twin-car hoists (a twin-car hoist is shown in Figure 19.30). Car size varies from small 2×3 -ft cars, which can take one or two passengers in addition to the operator, to large 7×15 -ft cars capable of carrying a great many passengers. Maximum typical payloads vary from 1000 lb for the small car to 7000 lb for the large car. Electrically powered (by in-car motors), various hoist models operate at speeds up to 100 to 400 ft per min. The large-car high-speed models, capable of hoisting up to 40 passengers, are designated for service on ultra-high-rise buildings.

For a climbing hoist to be used, a landing deck and gate must be installed at each floor of the building. As a safety feature, the car would not start moving until the gate has been closed. No gate at any floor can open while the car is in motion. A gate opens only after the car has reached that floor and come to a stop at the exact level of the gate. Next to each door is a buzzer or call button that is used to call the hoist for service. Radio communication is frequently used, as well. Modern hoists now feature advanced-technology control systems; for example, with the twin-car hoist, the system can store all calls from the floors and send the car that is nearest to the floor to pick up passengers, thus reducing waiting times.

Probably the most widely used form of powered access, self-propelled **scissor lifts** for construction sites (Figure 19.28) were developed from similar industrial lifts. These four-wheel-mounted lifts can be used on smooth concrete or similar solid surfaces or as rough-terrain equipment. Operated from the upper deck or ground, the lift serves the worker using it by also hauling tools and materials, depending on the kind of work performed (e.g., lifting plywood boards for slab formwork) (see Figure 19.28). The platform may be raised only vertically, but most models offer a slide-out platform extension for increased access capability, as well as removable guardrails for easier loading and unloading of materials. Scissor lifts are used where less reach and height but greater workspace and lifting capacity are required. They are designed to provide larger platform work areas and generally to allow for heavier loads than aerial work platforms of the boom type. Common platform height is in the range of 20 to 60 ft, and lifting capacity is in the range of 500 to 2500 lb.

FIGURE 19.28 Scissor lift in slab deck formwork.

Self-propelled **aerial work platforms** (often termed *boom lifts*) come in two main boom configurations: telescopic (straight) boom (Figure 19.29a) and articulated (knuckle) boom (Figure 19.29b). Reach is the main size identifier of these units; common maximum vertical reach is in the range of 30 to 120 ft, but some telescopic models extend as high as 150 ft. Common maximum horizontal reach is 20 to 60 ft; 80 ft maximum for the largest-size models. Lifting capacity of most models is 500 lb. Other than reach, machines also differ from each other in terms of maneuverability on various surface conditions and slopes, dimensions and their ability to move through narrow paths and operate in confined spaces, self-weight *vis-à-vis* load limits of the surface upon which they move and work, and platform size. Manufacturers offer a variety of standard and optional features that are likely to be used by workers performing their jobs from the platform. Examples include electrical outlets and air lines on the platform, as well as integrated generators with electric, air, and water lines running through the boom to the platform to power all kinds of tools (Hindman, 2005).

The articulated aerial platform is useful mainly for reaching up and over obstacles mounted on the floor and for reaching other elevated positions not easily approached by a straight boom. The telescopic, straight boom platform is especially useful for applications that require high reach capability. Booms of both types can be raised or lowered from vertical to below horizontal (although better under-reach can be attained with the articulated boom) and can be extended while the platform itself remains horizontal and stable. Articulated booms can often telescope their bottom or front section. In both boom-type machines, the operator can maneuver and steer the machine from the work platform even when it is fully extended and elevated.

19.9 Mechanized Form Systems

Mechanized cast-in-place concrete forming systems for specialized uses such as in bridge and tunnel construction have been in use for many years, and they are also widely used in the precast concrete construction industry; however, form systems for building construction, though increasingly industrialized and modernized, have not been mechanized for the most part. In fact, the classification of form systems as construction equipment, similar to other construction machines (such as cranes and pumps), is not taken for granted by many.

(a)

(b)

FIGURE 19.29 Aerial work platforms: (a) straight boom; (b) articulated boom.

Two exceptions of long-standing mechanized form systems used in building construction are hydraulic *tunnel* forms for the combined forming of walls and slabs, and vertical slipforms. Dating many years back and originating in Europe, tunnel forms are three-dimensional room-size systems suitable for the construction of orthogonal spaces in buildings that are designed in a repetitive pattern. Hotels and office buildings are typical examples, although tunnel forms have also been widely used in America since the 1990s in apartment-building construction. After the pour, when it is time to strike the forms, they are trapped in hardened concrete at the sides (walls) and above (ceiling slab). The hydraulic mechanism of the form is then actuated to retract the forms forcefully inward from the encapsulating concrete to allow their removal. Unlike tunnel forms, *slipforms* were not originally devised for building construction but rather for silos, chimneys, and similar vertical structures characterized by minimal horizontal projections interfering with the continuous vertical movement of the form. Slipforms, however, soon found use as

FIGURE 19.30 Crane-independent self-climbing forming system (Trump Tower, Chicago).

well in the forming of elevator and utility cores in high-rise buildings. Slipforming is covered in Chapter 10. The remainder of this section describes a newer mechanized form system for walls and other vertical building elements. Interchangeably termed a *self-climbing* or *automatic climbing* system, it is essentially a crane-independent system that uses hydraulics to raise itself from one floor of the building to the next (Figure 19.30). Unlike the slipform, which is attached to the fresh concrete throughout the process, the self-climbing form retracts from the hardened concrete wall before climbing to the next level. The climbing rails and other load-carrying components of the hydraulic mechanism are supported on the hardened walls of the lower level. Two main differences between this system and a slipform that relate directly to the system's primary designation as an automatic climbing system for use on buildings are that (1) it climbs by building floors, not continuously; and (2) it can accommodate horizontal elements, such as connecting slabs. Often nicknamed a *vertical plant*, it is perhaps the building form system closest to being considered equipment or a machine. Moving upward is a fully integrated, self-contained, three- or four-deck assembly, carrying a complete two-sided wall formwork system, climbing machinery, worker access platforms, material storage and reinforcing steel areas, weather protection and safety systems, and various worker utilities. Also available are provisions for concreting walls and slabs in one-pouring steps. These systems are not limited to building cores only and are often used for the entire vertical enclosure of the floors, offering integral solutions for column and beam formwork that are customizable for almost any façade design. If a climbing concrete placing boom is used, its climbing mast and running pipeline can be integrated in the climbing system, as well.

The climbing system is composed of several sections, termed *platforms*, depending on the size and layout of the system and the building elements formed by it (e.g., core walls only or entire building enclosure). Some climbing systems offer a central hydraulic system and climbing control such that the entire system can climb together. Other systems allow each platform to climb independently (as seen in Figure 19.30). Typically, these platforms carry 40 to 80 tons each; thus, the overall weight of the complete assembly carried up by the hydraulic mechanisms and supported by the host building can reach several hundred tons. The main advantages of these systems include: (1) savings in crane time required, (2) operability in bad weather and strong winds, (3) high production rates and fast progress, and (4) increased safety. Because of the considerable acquisition costs of these systems, they are viable solutions primarily for ultra-high-rise buildings (and other tall structures), where many reuses can be realized. A lower limit of 25 to 30 stories is the general rule of thumb; however, the economics of any specific use should be investigated by assessing the suitability of a particular system to the proposed architectural design, structural design, finishes requirements, use of other major equipment, weather, and more.

Acknowledgment

This chapter was written during the author's sabbatical as a Visiting Professor at the University of Wisconsin–Madison. The author is grateful for the hospitality of the UW Department of Civil and Environmental Engineering. Some of the technical information on certain equipment types was compiled from commercial manufacturer material available for free public use on the Internet. This availability is thankfully acknowledged.

20.1 Introduction

Roller-compacted concrete (RCC) has rapidly become a commonly used material for dams and massive structures. It is also used for overtopping and erosion protection of embankments and for heavy-duty pavements. This chapter concentrates on mass applications of RCC, primarily for dams; however, many of the concepts, from testing to material properties and mix designs, apply to all uses of RCC. In a sense, RCC dams can be thought of as a series of bonded pavements or parking lots stacked on top of each

* Consultant, Schrader Consulting Engineers, Walla Walla, Washington; expert in the theory and application of roller-compacted concrete, including planning, design, and construction of more than 100 international projects.

other. This chapter provides an explanation of what RCC is, how it differs from conventional concrete, what its special properties are, and how to use it effectively. The chapter covers specific technical and construction issues, including aggregates and mixture proportioning, laboratory testing, properties, engineering and design, cost, and construction. Emphasis is placed on areas of controversy and significant interest, such as cost savings, mixture proportions, material properties, watertightness, lift-joint quality, and design options.

20.1.1 What Is RCC?

Roller-compacted concrete is concrete, but it is placed by nontraditional methods. It requires a drier or stiffer consistency than conventional concrete. RCC can have a much broader range of material properties than conventionally placed concrete. It can use aggregates not meeting normal requirements, it can be placed at very high production rates, and it can be much less expensive. By definition (ACI Committee 207.5R, 1999), RCC is concrete that has a consistency that allows it to be compacted with a vibratory roller. Usually a 10-ton vibratory roller intended for compaction of asphalt and granular base is used because of its high compactive energy with high-frequency and low-amplitude vibration. RCC is often mixed in a continuous process rather than in batches. It is delivered with dump trucks or conveyors, spread in layers using a bulldozer, and given final compaction with a vibratory roller. Figure 20.1 shows a typical application of mass RCC on a medium-sized dam, using a 24-in. conveyor delivery system. A condensed summary of the RCC process has been described in earlier literature (Schrader, 1988; Schrader and Namikas, 1988). More thorough summaries have also been published (ACI Committee 207.5R, 1999; Hansen and Reinhardt, 1991; ICOLD, 1989; Jansen, 1989; Schrader, 1994, 1995c,d, 2002, 2003a). Freshly mixed uncompacted RCC generally looks like damp gravel that might be used for a road base, although some mixtures that have a wetter consistency look more like a conventional no-slump concrete. Not until the cement has reached a point near final setting or until the hydrated interior is exposed does RCC have the visual appearance of normal concrete. Portland cement is normally the primary cementing medium, although fly ash or natural **pozzolan** is often used for a major portion of the cementing material. Slag cement has also been used. Low-cement-content mixtures typically use natural nonplastic fines or rock dust as a filler to compensate for the lack of **paste** that would otherwise exist. At times, the fines have cementing abilities.

20.1.2 History

The rapid worldwide acceptance of RCC dams is a result of need, success, and economics. Materials used occasionally 30 to 40 years ago, in hindsight, could be considered to be RCC. These applications were typically stabilized gravel fills, and the material was not viewed as an engineered concrete. In the 1960s, a high-production, no-slump mixture that could be spread with bulldozers was used at Alpe Gere Dam in Italy (Gentile, 1964) and at Manicougan I in Canada (Wallingford, 1970). A similar process was used as late as the 1980s at Burdekin Falls Dam in Australia. These mixtures were almost RCC, but they were consolidated with groups of large internal vibrators mounted on backhoes or bulldozers, a procedure that is currently used at times with conventional low-slump mass concrete—for example, at the Tekeze Arch Dam in Ethiopia.

During the 1970s, a number of organizations were involved with trials, laboratory evaluations, and the development of various philosophies concerning mass RCC. A number of RCC applications for portions of dams and spillways, for temporary structures, and for noncritical uses were completed during this first decade of significant RCC development, including the placement of more than 1 million cubic yards of RCC at Tarbela Dam. In 1974, a preliminary design with extensive laboratory testing was completed by the U.S. Army Corps of Engineers for the Zintel Canyon Dam. This would have been the world's first RCC dam, but because of funding issues the dam was not actually constructed until 1992.

The work with RCC in the 1970s formed the basis for RCC dams as they began to appear in the 1980s. Growth and acceptance of this new process was dramatic. In 1983, only one major all-RCC dam existed in the world (Willow Creek in Colorado) (Schrader 1982a,b). About the same time, Shimijagawa Dam, a rolled-concrete dam (RCD) was completed in Japan. RCDs typically use RCC for the interior portions. By 1996, just 13 years after completion of the first all-RCC dam, about 200 large RCC dams worldwide were completed, under construction, or under design. There are now too many to keep track of, with many hundreds of projects being documented. In the United States alone, about 300 documented uses of RCC in dams can be found, including 46 dams higher than 50 feet, more than 30 dams lower than 50 feet, 126 uses of RCC to allow overtopping of embankment dams, more than 10 uses of RCC for added support of existing concrete dams, several for raising the height of existing dams, and several uses for earth-dam rehabilitation applications, among the many miscellaneous uses.

Although the United States initially had the greatest number of RCC dams, they are now more prevalent in countries such as China, Spain, and Brazil, and their popularity is increasing in Vietnam, India, and elsewhere in Asia and Southeast Asia. RCC dams can be found on every continent except Antarctica. RCC dams are in use, under design, or in the planning stages in countries that have climates ranging from arctic to tropical and are at elevations ranging from sea level to very high mountain regions. Figure 20.2 through Figure 20.9 show examples of completed RCC dams of various mixes, sizes, and locations.

Rolled-concrete dams are now being used extensively in Japan, where over 30 projects have been completed, are under construction, or are in various stages of planning and design; however, RCD has not become popular outside of Japan. The process uses a relatively low-cement-content RCC for the interior portion of the dam, but typically encases the entire mass of RCC with at least 10 ft of conventional concrete. This includes the upstream and downstream faces, the foundation, and the upper portion of the dam, although the current trend seems to use more RCC and less conventional concrete. **Monolith** joint spacings are typically the same as those used for conventional concrete dams. The result is a very attractive dam that looks and behaves like a traditional concrete dam, but the RCD procedure tends to compromise the substantial cost savings and reduction in schedules possible with dams that are almost entirely RCC. The trend in the United States has moved from using RCC primarily for new dams to using it more for rehabilitation and support or the buttressing of existing dams, for raising the height of existing dams, and for providing emergency spillway capacity over existing embankment dams. This trend is expected to develop in other countries as they begin to realize the benefits and additional uses of RCC. Figure 20.10 shows the use of RCC to provide a buttress and an overtopping spillway at the Tongue River embankment dam in Montana.

FIGURE 20.10 RCC used to provide a buttress and overtopping spillway for the Tongue River embankment dam in Montana. The mix primarily used 150 lb of cement (no ash) with surface layers of the stilling basin having higher cement content.

As with conventional concrete, there is no known limit to the size or height of dams that can be designed and constructed with RCC. Currently, dams on the order of 300 ft high are common, and dams about 600 ft high are not unusual, such as the 620-ft Miel I dam in Colombia. Very large dams such as Longtan in China and Gibe III in Ethiopia are beginning to emerge. Dams up to about 900 ft high, with nearly 20 million cubic yards of RCC are also being designed, such as Diamer Basha in Pakistan. The performance of RCC dams has been very good, although like other dams some projects have had issues with regard to cracking and seepage (Schrader, 1988, 1994, 1995a,c,d, 2002, 2003a; Schrader and Namikas, 1988). These two specific issues are discussed later in more detail.

20.2 Advantages and Disadvantages

20.2.1 General

The list of RCC dam advantages is extensive, but some disadvantages should be recognized. Some of the potential advantages can only be realized with certain types of RCC mixtures, structural designs, production methods, weather, or other conditions. Likewise, some disadvantages only apply to certain conditions and types of mixtures. One condition that remains constant with RCC is that each job must be thoroughly evaluated on its own. What is advantageous for one project with a given set of conditions may not be advantageous for a different project, and what is a problem at one location may actually be a benefit at another location. No single design, mixture, or construction method is ideal for all projects. Although it is almost routine for efficiently designed RCC dams to be the least costly alternative when compared to other types of dams, in some circumstances RCC may be more costly. A situation in which RCC may not be appropriate is when aggregate material is not reasonably available but an abundance of good material is available for impervious fill. When a large spillway capacity is necessary, RCC dams usually are the most economical because the spillway can be placed over the dam, and the non-overflow portion of the dam can be allowed to overtop in an emergency. Fill and embankment dams typically require a separate, very expensive spillway excavated into an abutment and, because they cannot be allowed to overtop, they usually have added height to ensure that overtopping is avoided.

20.2.2 Cost

Typical reasons for using RCC are the reduced cost and time it offers. Savings can be dramatic, sometimes in excess of 50%; however, in reality, some projects lacking the proper planning, equipment, and supervision have not saved any time, and the potential cost savings have been lost. Some projects have experienced added costs because of design decisions by the engineer or owner that resulted in expensive or time-consuming options—for example, architectural concrete, nonessential extra nonessential galleries, excess conventional facing concrete, elaborate spillways added to the face of the dam after finishing the RCC, and arbitrary decisions to use imported or excessive cementitious materials and expensive aggregates when they really were not necessary. Each project must be evaluated on its own. A trade-off in appearance and other characteristics that may be associated with high costs must be acceptable to the owner and compatible with technical requirements.

It is difficult to obtain final actual cost data for RCC dams, although bid price data for various portions of the RCC are abundant, and several reasonable summaries of approximate overall costs are available in various references (Forbes, 1988; Hansen and Reinhardt, 1991; Schrader, 1988, 1995c,d; Schrader and Namikas, 1988). Apparent discrepancies in costs reported in publications and in costs discussed at various meetings exist for two primary reasons: First, the work and materials included in the costs can be very inclusive (e.g., mobilization, joints, engineering, facings, diversion, spillway, forming, galleries, drains, foundation preparation), or the costs may include only the very basic costs of RCC production (aggregate, cement, mixing, and placing). Second, costs are sometimes based on unit bid prices, which can be unbalanced and not the true prices and do not include subsequent added costs for claims, litigation, time extensions, modifications, and overruns.

TABLE 20.1 Typical RCC Prices (1996 U.S. Dollars)

Volume (yd ³)	Price per yd ³
1000–6000	\$42–94
30,000–100,000	\$34–42
250,000–500,000	\$23–34
1,000,000–7,500,000	\$22–29

Note: Prices include RCC, facings, conventional concrete, and miscellaneous items.

Because of the many interrelated aspects of RCC, a fair way to compare the costs of various designs and projects is to consider the volume and combined cost of applicable mobilization; access and haul roads for RCC and related activities; cement; pozzolan; aggregate; admixtures; mixing; delivery; placing; compaction; grout-enriched or bedding mixtures; lift-surface cleaning; curing and protection; upstream and downstream facings; watertightness; spillways; joints; detailed work at the top of the dam; foundation preparation, including leveling the concrete if used; galleries; drainage; and cooling or crack mitigation, if required. Consideration should also be given to the required quantity of excavation, as well as the length of diversion and outlet structures.

The reason for this comprehensive comparison is that misunderstandings have occurred without it. An example is when comparing a more massive lower strength design to a less massive higher strength design. The low-strength design may have significantly lower RCC unit costs, but high dams may require greater volume, more excavation, and longer conduits. Lower unit costs are usually the result of greater volume, lower strengths, and reduced aggregate, cement, pozzolan, and admixture requirements. High-strength designs typically have greater unit costs. They may also have significantly more foundation treatment, **gallery** requirements, lift-joint requirements, leveling concrete, monolith joints or crack control, and cooling requirements. Another example is a design that requires more costly and complex RCC placing methods but has the benefit of less costly spillway and facing work, whereas a different design may have very simple RCC placing that then requires time-consuming and costly spillway or facing construction.

Even with these problems, general price guidelines can be provided. Typically, the final price of RCC (all ingredients, mixing, delivery, and placing, including joint treatment, drains, cure, facings, and other directly related items) varies from about \$22/yd³ to \$94/yd³ (1996 U.S. dollars), depending on the size of the project, strength, and complexity. Table 20.1 provides typical price ranges for different sizes of dams based on historical records of completed projects and estimates for future projects. The table excludes projects in France, where RCC tends to be more expensive than elsewhere (but still locally competitive). Another exception is the relatively high final cost of the high-cementitious-content RCC at Upper Stillwater Dam (Parker, 1992). Exceptions at the other end of the spectrum are Zintel Canyon Dam and Willow Creek Dam, where uncomplicated projects resulted in final real costs less than the range indicated in Table 20.1.

Table 20.2 provides a typical price breakdown (1996 U.S. dollars), showing where the more expensive aspects of RCC typically lie—namely, in aggregate and **ementitious** materials. The table also demonstrates the increased unit cost of RCC with a higher cementitious content, but also the typical lower volume required for a high-cementitious-content dam compared to a low-cementitious-content dam. Historically, and in estimates of future projects, the final cost of an entire dam with all related construction such as outlets, spillway crests and gates, access, foundations, diversion, instrumentation, valves, finishing, and environmental restoration is usually about 1.5 to 2.5 times the cost of the RCC. The reasons are different from job to job, but the range stays the same. Simple designs with unformed faces and more massive sections tend to be less, while more complex designs and smaller sections tend to be more.

A big part of the savings of RCC dams compared to embankment dams comes from incorporating the spillway into the dam rather than having a separate major excavation and structure. Additional major

TABLE 20.2 Example RCC Price Breakdown (1996 U.S. Dollars)

Item	Lower Strength, More Massive (\$/yd ³)	Higher Strength, Less Massive (\$/yd ³)
Aggregate	11.45	13.20
Cement + pozzolan	7.25	12.75
Delivery	2.80	3.00
Mixing	1.50	1.60
Cooling	.20	1.40
Place-spread-compact	.55	.60
Cure and protection	.20	.15
Bedding and special mixes	.40	.05
Cleaning and surface prep	.25	.10
Survey, joints, drains, gallery, miscellaneous	.20	.40
Total	24.80	33.25
RCC volume (yd ³)	1,000,000	850,000
RCC cost for dam	\$24,800,000	\$28,262,000
Total dam	\$28.60	\$38.60
Total volume (yd ³)	1,030,000	880,000
Total concrete	\$29,461,000	\$33,968,000

savings are related to the speed of construction. Often, the dam can be raised in one dry season, thereby greatly reducing the diversion and cofferdam costs when compared to the costs of providing protection during the wet season for other designs. When a large project can be completed with RCC sooner than the completion date for an alternative type of dam or design, the savings resulting from lower interest payments for borrowed money during construction can also be significant. The additional income from earlier completion and earlier water storage can be extraordinary for large hydroelectric and irrigation projects. On the other hand, due to weather, lack of availability of cementing materials, funding limitations, or, more frequently, inappropriate equipment, some RCC projects have finished well after the originally projected completion date. If, however, the factors that impacted RCC production occur with an alternative design, the outcome for the alternative can usually be shown to be even worse than it might have been for the RCC dam.

20.2.3 Schedule

In addition to the cofferdam and diversion benefits, being able to schedule RCC placement for dry seasons improves the efficiency of construction. RCC can occasionally remove the dam portion of a large project with tunnels and powerhouses from the critical path and can allow a delay in the start of dam construction, thereby saving interest on that portion of the work. Typical placing rates for projects having RCC volumes on the order of 10,000 to 25,000 yd³ are about 50 to 200 yd³/hr. Medium-sized projects of about 50,000 to 200,000 yd³ generally achieve rates of about 150 to 400 yd³/hr. Large projects of about 400,000 to 2,000,000 yd³ or more can be expected to achieve about 500 to 1000 yd³/hr. In most cases, especially with medium-sized projects, the time required to mobilize, produce aggregates, and prepare foundations exceeds the time required to place the RCC. Emergency projects have benefited from the speed of RCC construction. Kerrville Dam in Texas utilized RCC for the rapid construction of a new dam downstream of an embankment dam that was in imminent danger of failure due to overtopping; the design and construction were accomplished in a matter of weeks. Concepcion Dam in Honduras used RCC to build a water-supply project after declaration of a national emergency in the capitol city of Tegucigalpa (Giovagnoli et al., 1991, 1992). Burton Gorge Dam was essentially investigated, planned, designed, constructed, and put into operation in less than 1 year (Schrader, 1999b).

20.2.4 Equipment, Materials, and Manpower

The construction equipment required for RCC is usually available, including appropriate mixers and conveyors, which are the more difficult pieces of equipment to locate and may have to be imported. Depending on the approach taken in the design and location of the project, materials required for RCC may be difficult or very simple to procure. For example, the design of Concepcion Dam took into account the poor quality of the aggregate, cement, and pozzolan so local materials and a low-strength mixture could be used for economical construction without delays (Gaekel and Schrader, 1992; Giovagnoli et al., 1992, 1992). These materials could not meet normal requirements for conventional concrete or for RCC requiring medium to high strengths. If the design had not been adapted to materials that were readily available, a much more expensive RCC dam would have resulted that utilized specially produced cement and pozzolan and very expensive aggregates that would have been hauled a long distance. A similar situation developed at Mujib Dam in Jordan, where the original design with higher quality aggregate and imported fly ash was changed to eliminate the need for imported fly ash (or any purchased pozzolan) and to allow for the use of more economical dirty basalt aggregate (Schrader et al., 2002, 2003a). A similar approach was also used at the Burnett River Dam in Australia (Herweynen et al., 2004; Lopez et al., 2005). The redesign of Rompepicos Dam in Mexico also used this approach with regard to both cementitious content and aggregates (Schrader and Bali, 2003). Other examples are discussed in Section 20.3.1.

Roller-compacted concrete dams can be built by labor-intensive methods with reduced equipment requirements, but this should only be considered for smaller projects where economics and political reasons justify it and where relaxed quality can be tolerated. RCC is best suited to high production with large equipment and a small labor force. Even where labor is inexpensive and readily available, experience has shown that it is best to use a small work force. It is essential for supervisory staff to understand RCC as well as the type of dam construction to be used. Laborers do not require special skills other than those found in the general heavy-construction industry, but they should be given an orientation for special concerns when handling RCC. It is common for contractors new to RCC to use the services of a specialist familiar with RCC to assist at the start of placing.

20.2.5 Weather

Rain and hot weather are arguably the biggest problems in RCC production, but they are not insurmountable. For a variety of reasons, including the impact of weather on production or hauling, aggregate supply and the reliable delivery of cementitious materials have also been factors in slowing or stopping RCC production on some projects. Many major RCC projects are located in tropical and desert climates. Hot weather causes higher internal peak temperatures, but if the environment remains warm and does not have a severe cold season, thermal cracking can usually be avoided without extraordinary cooling measures for the mix, at least for mixes designed to have relatively low cementitious contents. Hot weather also reduces the allowable time before the concrete must be delivered, spread, and compacted, as well as the time that a lift surface can be exposed before it starts to suffer a significant loss of quality. Rain can be a significant problem if it is heavy or if equipment drives across the concrete surface when it is wet. Light rain will not significantly damage a compacted surface if conveyor delivery is used and hauling equipment is not driving over and disturbing the surface, but it can be a major problem if haul vehicles are used to deliver RCC on a damp lift surface. Rain problems are minimized by scheduling RCC placing during the dry season, avoiding placing during hours when rains are common, providing rain protection when appropriate, and using very high production rates with high-speed conveyor delivery. Table 20.3, developed by the author based on actual production records of different types of RCC dams in various climates, provides general guidance concerning the probable amount of time that an RCC project will be down as a result of rain. As shown in Table 20.3, downtime is a function of rain intensity and duration as well as the method of delivery. If trucks are used for delivery and they must operate on the RCC surface, rain is a much more significant problem compared to when an all-conveyor delivery system is used. This is because tire traffic on a wet surface causes the surface to develop a slurry that then must be removed before placing the next layer, or the dam must be designed with consideration for the decreased lift-joint quality if adequate cleaning is not done.

TABLE 20.3 Shifts Lost Because of Rain

Method	Peak Rain Intensity (in./hr)				
	0	0 < 0.04	0.04 < 0.08	0.08 < 0.20	<0.20
Haul vehicles on dam	0	0 ^a	1 ^a	1 ^a	2
All-conveyor delivery	0	0	0	0 ^a	1 ^a

^a Add one more lost shift if rain duration is greater than 8 hr.

Note: Assumes a two-shift/day work schedule.

20.3 Aggregates and Mixture Proportions

20.3.1 Aggregates

With respect to grading and other properties, aggregates similar to those used in conventional concrete can be used for RCC; however, materials and gradations that would normally be considered totally unacceptable for conventional concrete have been used very successfully in RCC dam construction and can actually be advantageous. Although aggregates meeting normal concrete requirements can be used, they are not necessary in RCC dam construction. Because there were no economical options, Concepcion Dam, discussed earlier in Section 20.2.4, has the unique honor of successfully using probably the worst quality materials in a major concrete dam. Monksville and Copperfield Dams used unwashed gravels with minimal processing. The aggregate included friable particles of decomposed granite in the sand sizes. Middle Fork Dam used marlstone oil shale with a specific gravity of about 2.2, a high Los Angeles abrasion loss, and absorption of 12 to 20%. In this case, an unlimited supply of this rock was available at the dam, whereas the nearest aggregate that met traditional criteria for concrete was expensive and required a long haul, all up steep grades. The marlstone required a slightly increased dam section and volume, but the overall result was a large savings.

Willow Creek Dam was the first of many projects to use dirty overburden and dirty quarry materials that normally would be wasted or require extensive washing. As discussed earlier, the fines that normally would be washed out of traditional concrete aggregate are actually needed to achieve a low cementitious content in the RCC mix. Each project must be evaluated separately to find out how to best use the available aggregate materials. In some cases, such as where a poor foundation controls the design section, a low density may actually be beneficial. In most cases, fines are beneficial, especially if they tend to be pozzolanic and well graded. The fines should be nonplastic. Some low-strength aggregates may produce a low but tolerable strength along with a desirable high creep and high strain capacity. High Los Angeles abrasion losses can usually be accepted because of service conditions, the mixing and compacting equipment, and the typical RCC grading.

Roller-compacted concrete mixtures are less affected by particle shape than are conventional concrete mixtures because of the mixing and delivery equipment used and the typical grading. The presence of flat and elongated particles is still undesirable, but amounts up to about 40% on any sieve size with an average below about 30% for all sieve sizes have been acceptable. Both crushed and rounded materials work well, but the ideal combination appears to be angular crushed coarse particles with natural rounded sand. When steep unformed slopes are to be constructed, crushed material becomes more important.

Alkali-aggregate reaction in RCC is a subject in itself. A few comments are made here. Potentially reactive aggregates have been used in RCC without problems for various reasons, including low cement contents and high pozzolan contents in some mixtures and the use of low-alkali cements when available. A nontraditional concept to consider is that a slight expansion due to the alkali-aggregate reaction can actually be beneficial if it offsets thermal contraction.

The key to controlling segregation, minimizing cement contents, and providing a good compactable mixture begins with a grading that is more uniform and contains more material passing the No. 4 sieve than would be common in conventional concrete. Using concepts from conventional mass concrete,

^a Adjust the maximum and minimum percent passing the No. 200 sieve on a combined gradation as follows: up 1% if the cement plus ash content of the RCC is less than 120 lb/yd³; down 1% if the cement plus ash content of the RCC is more than 240 lb/yd³.

^b Total paste is all materials in the full mixture with a particle size smaller than the No. 200 sieve (see text).

^c Total cementitious materials consists of pozzolanic cement having approximately 15% natural pozzolan.

earlier projects tended to use 3-in. maximum size aggregate (MSA), but the recent trend has been to use smaller MSA, on the order of about 1-1/2 to 2 in. This reduces segregation, improves lift-joint quality, and reduces equipment maintenance. The reduced MSA arguably can cause a minor reduction in strength, but such a reduction is minimal and not as significant as would be expected in conventional concrete.

It is inappropriate to provide a single set of upper and lower gradation limits that could be considered correct for all RCC. A wide range of gradations has been used successfully. Table 20.4 shows some example gradations that have been used in RCC. The mixture-proportioning concept that uses a low cementitious content and requires fines in the mixture ideally has a grading similar to an impervious gravel with nonplastic fines. Mixes with lower cementitious content generally require more fines. The maximum amount of fines that can be added without a reduction in strength, and without causing the RCC to become too sticky to mix, spread, and compact, depends on the plasticity of the fines. Plasticity can be defined in terms of soil mechanics by the liquid limit (LL) and plastic index (PI). Based on the LL and PI, Table 20.5 has been developed and used over the past 30 years as a guide for the maximum amount of fines that can be included for most RCC mixtures.

20.3.2 Mixture Types and Designations

Roller-compacted concrete suitable for use in dams can be made with very low cementitious contents, on the order of 85 to 150 lb/yd³, or it can be made with very high cementitious contents, on the order of 200 to 425 lb/yd³. Both options, plus intermediate cementitious contents, have been used quite successfully on low and high dams, both options continue to be popular, and both are expected to be used in the future (Schrader 1994, 1995c,d, 2002, 2004). The decision-making process for selecting the type of mix is not very dependent on the size or height of the dam. Unfortunately, it is often more related

High	200–425	2500–4500

to the simple issue of what the designer or owner has used in the past. The decision should be based on factual information related to foundation quality, the degree of reliable inspection expected, facing techniques, climate, cooling and thermal issues, the age at which the reservoir will be filled, and available materials with their associated costs and quality. The best overall option might be a higher strength, high-cementitious-content mix with less mass in one situation, but it could be a lower strength, low-cementitious-content mix in another situation.

Dams designed with higher cementitious content mixes may have slightly less volume but typically have a much higher unit cost and more stringent cooling and quality-control requirements. Lower cementitious content mixtures typically have lower unit costs and less stringent quality control but may require more mass. They also may require special attention to achieve watertightness along lift joints. Costs and watertightness are discussed elsewhere in this chapter. Higher cementitious content mixtures tend to result in good cement efficiencies (strength per unit of cementitious material) when compared to conventional concrete, but lower cementitious content mixtures tend to have even greater efficiencies, on the order of about 10 to 20 psi/lb of cementitious material in a cubic yard of RCC. Efficiencies on the order of 10 psi/lb are typical for excellent quality conventional concrete.

The American Concrete Institute's subcommittee on RCC has recently completed its proposed latest major update on RCC for massive structures. The new report is intended to identify low-, medium-, and high-cementitious-content mixes by a combination of cementitious content and strength ranges that are consistent with other publications. There is a deliberate overlap for the different cementitious content designations, allowing flexibility in judgment with regard to whether the aggregate fines provide some cementitious or pozzolanic value. Nonetheless, the designations, shown in Table 20.6, provide useful guidance.

TABLE 20.7 Types of RCC Mixtures: Typical Extremes

	Dry, Low Cementitious		Wet, High Cementitious	
	lb/yd ³	ft ³	lb/yd ³	ft ³
Cement	100	0.51	150	0.76
Pozzolan (ash)	0	0.00	250	1.60
Water	185	2.96	180	2.88
Air (0.5%)	0	0.14	0	0.14
Aggregate fines (8%)	280	1.80	0	0.00
Total paste	565	5.41	580	5.38
Percent paste	14%	20%	14%	20%

Note: Pozzolans and fines may or may not be cementitious in RCC.

At times, terminology has referred to RCC as being high or low *paste content* rather than having high or low *cementitious content*. This is an inaccurate description of the different types of RCC mixes (Schrader, 1994, 1995c,d, 2002, 2003a, 2004). Although RCC mixtures have high, medium, and low cementitious contents, they should not have high and low paste contents. All RCC mixtures should have at least 20% paste by volume (about 14% paste by weight), with the recent tendency being toward paste contents on the order of about 21 to 23% by volume. Paste is considered to be all of the materials that constitute the pasty portion of the mix. This includes everything smaller than 75 μm —small air bubbles, water, admixtures, pozzolans, cement, and aggregate fines.

If low-cementitious-content RCC is used, aggregate fines are necessary to supplement the otherwise deficient paste content. If a high-cementitious-content RCC is used, clean aggregates are required to keep the paste content from being too high. If the paste content is too low, low strengths, excess water demands, and segregation can be expected. If the paste content is too high, inefficient use of cementitious materials can be expected (i.e., less strength per pound of cementitious material). Mixes with too much paste can also result in lift surfaces with excess paste and laitance at the lift surface after compaction, thereby requiring lift-joint cleaning similar to that used for conventional concrete. Table 20.4 and Table 20.7 demonstrate the concept of constant paste contents for all types of RCC. They compare two extreme examples of RCC mix types and consistency. These examples are from two early RCC projects that used mixes near the extremes: (1) the very dry, lean Willow Creek Dam, and (2) a mix similar to one of the very high-cementitious-content, wet-consistency mixes at Upper Stillwater Dam.

Roller-compacted concrete mixtures can have low or high pozzolan contents. Current use ranges from 0 to about 80% pozzolan. There is no universal optimum. In some cases (such as for Stagecoach Dam), using 100% cement resulted in lower strengths than using essentially the same total cementitious content (cement plus pozzolan) but with 50% of it being pozzolan. In other more common cases, adding pozzolan while keeping the cement constant has actually caused a reduction in strength or no significant strength change. Some examples are the Burnett Dam (renamed Paradise dam) (Herweynen et al., 2004; Lopez et al., 2005), the Mujib Dam (Schrader et al., 2003a), the 358-ft high Rompepicos Dam (Schrader and Bali, 2003), and the recently completed mix studies for Dong Nai 3 Dam in Vietnam. In each case, an initial arbitrary decision had been made that a mix with high pozzolan content would be best and worth the extra cost; however, when the cost and difficulty of obtaining good-quality pozzolan were finally appreciated, tests without pozzolan were done that showed that not only was the use of pozzolan costly and unnecessarily complicated but the pozzolan also caused a reduction in strength compared to some mixes with the same cement content but no pozzolan.

The long-term strength gain of RCC is not necessarily determined by the amount of pozzolan that is used, as would normally be expected with traditional concrete. For example, a lean RCC mix at one project using only 92 lb of cement per cubic yard and no pozzolan resulted in 1-year strengths that were 380% greater than the 28-day strengths, while other mixes with pozzolan at other projects have achieved strength gains of only about 150% over the same time period. Figure 20.11 and Figure 20.12 show the global range of values that have been experienced for different pozzolans with different RCC mixtures.

FIGURE 20.11 Efficiency of cementitious material as a function of pozzolan.

FIGURE 20.12 Long-term strength increase as a function of pozzolan.

Another observation concerning RCC is that some projects have required a minimum cementitious content of about 50 to 100 lb/yd³ to gain good strength efficiency (strength per pound of cementitious material), whereas at other projects the efficiency has been relatively constant from 0 to about 150 pounds of cement per cubic yard of RCC. Overall, strength efficiency typically tends to decrease at high cementitious contents for the same aggregates and materials at any given project, as shown in Figure 20.13. Strength as a function of total cementitious content is shown in Figure 20.14.

The important point is that RCC does not follow the same rules and trends as conventional concrete with regard to optimum cementitious and pozzolan content. Each project should be evaluated on its own merits, with its own materials, and with a wide range of options during the initial investigations. Open mindedness on the part of decision makers is essential. They should not be misled by old traditional concrete experience or guidelines or experience with only one type of RCC.

FIGURE 20.13 Reduced strength efficiency as a function of increased cementitious content.

FIGURE 20.14 Example effect of moisture content.

20.3.3 Fresh Mixture Consistency

The terms *wet* and *dry mixture consistency* can be a source of confusion. RCC mixtures have no slump. They must be stiff enough to support a large vibratory roller. By traditional concrete standards, all RCC has a dry consistency; however, within the RCC community, mixtures are referred to as being wet or dry on the basis of their appearance and how they behave in the fresh state during and after compaction. Roller-compacted concrete mixtures that are considered to be wet generally produce a weaving effect or surface waviness as rollers and trucks drive across the freshly compacted RCC. This is due to an excess of moisture or the use of more water than necessary to fill all of the void space. Internal pore pressure develops in the fresh mixture, similar to what occurs in some soils. By contrast, mixtures that are considered to have a dry consistency generally do not weave under traffic after compaction. The terms

FIGURE 20.15 Example effect of moisture content.

wet and *dry* reasonably describe the behavior of the mixture, but they do not indicate whether the actual water content is high or low. Because of differences in aggregate (texture, shape, and grading) and in cements and pozzolans, the effects of fines when they are included, and the influences of temperature and humidity, a mixture with a higher water content can actually be drier in appearance than another mixture with a lower water content and *vice versa*. This is true when considering water in excess of the water absorbed by the aggregate, and it can be even more exaggerated when total water contents based on oven-dry aggregates are considered. Table 20.7 contains an example.

20.3.4 Water/Cement Ratio and Optimum Water Content

Although it is a somewhat controversial issue, the well-known water/cement ratio rule for traditional concrete does not necessarily apply to RCC. In fact, if what appears to be an excessively high water/cement ratio in a lean mix is decreased too much by simply reducing the water content, it will result in decreased strengths and poor-quality material resulting from inadequate moisture for compaction. As with embankment materials and soils, there is an optimum moisture, as shown in Figure 20.15. At this optimum, both strength and density are maximized. The shapes of the moisture vs. density and moisture vs. strength curves help establish the probable type of mix for a project. If the curve is fairly flat, adding more water will have little harmful effect on the strength of the RCC mass while improving the more important lift-joint quality. In this case, the wetter mix is desirable. If the curve drops off sharply at moisture contents above optimum, a drier-consistency mix is probably best.

For other reasons, the designer may stipulate in advance that a wet or a dry consistency mix is desired. Typically, dry-consistency mixtures are at or near optimum moisture. They typically have modified Vebe times (ASTM C 1170) in excess of 30 sec when that test is used for workability with a surcharge weight. These mixes have very little, if any, deformation under truck and tire traffic after rolling; however, the freshly compacted surface of these mixes can be damaged by truck traffic due to abrasion and turning of the tires. This damage typically can be removed by blowing with an air hose. Dry mixes typically do not have any bleeding problems and are essentially impervious to rain when they are compacted. Rain will simply collect on the surface. If there is any vehicular traffic or other surface disturbance, however, free water on the lift will begin to seriously damage the lift.

Typically, wet-consistency mixtures have modified Vebe times, on the order of about 10 to 15 sec, and they are much wetter than the optimum moisture content. Because they have more moisture than needed for maximum density, there is an excess of water within the compacted RCC. This water has no place to go, so it tends to develop a slight amount of free surface moisture at the lift surface. This can leave a pasty material and surface laitance that requires cleaning. These mixes easily weave under the roller because of

FIGURE 20.16 Surface damage caused by truck tires on wet-mix RCC.

FIGURE 20.17 Interior damage caused by truck traffic on wet-mix RCC.

internal pore pressure caused by the extra water. They also weave under truck or other vehicular traffic until the mix sets sufficiently to support the traffic. A serious issue is when trucks are used to deliver the RCC and must drive across wet mixes, because for a period of time when the mix is between initial and final set when the cement is hydrating and beginning to harden it has insufficient strength to support truck traffic. The result is that the cement paste is disrupted and damaged as it deforms under tire traffic while it is trying to set. This shears and breaks the mortar matrix. The strength loss cannot be regained. The problem can be apparent at times due to cracking at the lift surface next to tire ruts, as shown in Figure 20.16. The more significant problem of internal damage to the RCC can only be seen by saw cutting into the mass afterwards to expose the internal damage as shown in Figure 20.17 (Schrader, 2002).

Because the optimum moisture for RCC is established primarily by the aggregates (there is little or no change in optimum moisture as the cementitious content is adjusted up or down), any major change in water/cement ratio can only be accomplished by increasing or decreasing the cementitious content,

TABLE 20.8 Water/Cement Ratio Examples for Dry-Consistency Roller-Compacted Concrete

Maximum Size Aggregate (in.)	Cement + Fines (lb/yd ³)	Water (% above saturated surface dry)	W/(C + F)	W/C ^a
3	80 + 32	4.4	1.63	1.47
3	175 + 00	4.5	1.06	1.06
3	175 + 80	4.5	0.73	0.65
1-1/2	315 + 135	4.8	0.44	0.39

^a Water/equivalent cement ratio if the ash volume was cement.

as shown in Table 20.8. When nonapplicable experience from conventional concrete is used to arbitrarily apply a low water/cement ratio requirement to the RCC, the result will be higher cementitious contents with associated higher costs, increased heat and thermal stresses, and a more brittle **elastic modulus** with less stress relaxation due to creep. Attempts to change the water/cement ratio by changing the water content have only minor effects on the water/cement ratio, and such changes can alter the mix consistency and cause deviations from the optimum or desired moisture content and compactability. If the cementitious content is low, the water/cement ratio must be high. Values on the order of 1.0 to 2.0 are common in RCC. This is a major deviation from traditional water/cement ratios in conventional concrete that are more on the order of 0.4 to 0.6. This high water/cement ratio with lean RCC is normal. It does not imply low-quality concrete. It implies a low cementitious content rather than a high water content and wet mix consistency.

Data have been reported implying that a high water/cement ratio automatically causes a major reduction in RCC strength. This erroneous conclusion is the result of incompletely reporting all of the data. As the water/cement ratio decreases, strengths were shown to go up dramatically, but this was primarily because the water/cement ratio was decreased by increasing the cementitious content while keeping the water and mix consistency essentially constant. Figure 20.18 shows the complete picture, with the strength shown as both a function of water/cementitious ratio and as a function of cementitious content.

20.3.5 Approaches to Mixture Design and Proportions

Roller-compacted concrete mixture proportions should follow the convention used in traditional concrete—that is, identifying the mass of each ingredient contained in a compacted unit volume (cubic yard) of the mixture based on saturated surface dry (SSD) aggregate conditions. Moisture contents are then typically converted to a percentage of water above SSD aggregate conditions divided by the compacted

**FIGURE 20.18** Strength vs. water/cementitious ratio and cementitious content.

density of the total RCC mixture. Confusion has occurred when some publications and engineers have based the water content on the oven-dry aggregate mass, as done for soils, or on some other parameter. Care should be exercised when reviewing the literature. Mixture proportioning for some earlier projects relied on making many mortar cubes with varying cement, pozzolan, water, and admixture contents in an effort to optimize the mixture without making cylinders of the full mixture. This approach can be very misleading. Experience at several projects has shown that mortar cubes do not necessarily indicate how the full RCC mixture will perform. In some cases, mortar cubes have actually indicated the opposite of what ultimately happened with the full RCC mixture (Gaekel and Schrader, 1992).

Mix designs for RCC can be approached in many ways (ACI Committee 207.5R, 1999; Herweynen et al., 2004; Lopez et al., 2003a,b; Rizzo et al 2003; Schrader, 1994, 1995d; Schrader et al., 2003b; Tatro and Hinds, 1992); see Schrader (2004) for a comprehensive summary. One procedure is based on the concept of water/cement ratio. Another procedure uses a series of lab mixtures to pinpoint the optimum cementitious and pozzolan contents for a given set of aggregates. Other procedures are basically variations of these two themes. No single approach to mix design is best for all situations. All approaches to mix designs ultimately require full-scale job trials and tests, with adjustments based on the results of those tests.

The term *soils approach* has been erroneously used by others to describe a mix-design method developed by the author. This method has nothing to do with soils, and the term is misleading. All methods of RCC mix design, including the one mislabeled as the soils approach, treat the material as a no-slump concrete. They all use a suitable controlled gradation aggregate. They all intend to optimize the amount of pozzolan (if used). They all produce a consistency suitable for RCC construction. They all determine basic concrete material properties such as density and strength.

Whichever procedure is used for mix designs, the method of making test samples must be suitable for the type of mixes that will be made. Some methods, such as the vibrating table, are suitable only for wetter and higher paste mixes, whereas the pneumatic tamper and Kango or Hilti hammer are suited to drier and lower paste mixes. Some laboratories have concluded that a drier or leaner mix is not suitable for a particular project when in reality the mixes were actually quite suitable but the lab had made the samples with the wrong equipment (Schrader, 2003b).

20.3.6 Chemical Admixtures and Grout-Enriched RCC

Chemical admixtures have not been very effective in low-cementitious-content and dry RCC mixes that do not exhibit a fluid paste when subjected to vibration under full consolidation (Gaekel and Schrader, 1992; Schrader, 1984). If enough water is added to cause a fluid paste, retarders have been useful and water reducers have worked, but this may require very high admixture dosages on the order of 3 to 12 times the normal rate. The benefit of retarders and water reducers must be balanced against the cost, the complication of an additional ingredient, and any strength reduction associated with additional water required to provide the necessary wetter paste consistency. Most wetter consistency and higher cementitious content mixes depend on both the high cementitious content and a retarded set time to achieve good lift-joint quality and impermeability for the design. In this case, when the next layer of RCC has to be placed before the previous layer sets, a wetter consistency mix with high doses of retarder and a usually high pozzolan content is usually unavoidable.

As discussed further in Section 20.4.6, field experience has shown good or tolerable resistance to most natural freeze–thaw exposure conditions of mass RCC without air entrainment, but the option of using entrained air has now been achieved with some mixtures. Again, the benefits should be balanced against the disadvantages and cost for each application. Air entraining has been difficult to accomplish with RCC on a routine and consistent basis, but it has been done in the United States using special admixtures such as synthetic air, and it has been accomplished in China (Chengqian and Chusheng, 1991).

Many efforts have been made to consistently entrain air in RCC at facings by using grout-enriched RCC (GERCC). After the mix has been spread, a fluid grout is added to the RCC, with the intent being for the grout to mix uniformly throughout the RCC and turn it into a more fluid mix with higher cementitious content. The result is a zone of material (usually against a form at the face of the dam) that

FIGURE 20.19 Twenty-eight-day strength vs. percent compaction.

will have properties and appearance similar to conventional concrete. Various procedures have been used, from simply pouring a hand-mixed grout onto the surface and using an internal poker vibrator to mix and consolidate the RCC with the grout to using sophisticated grout pumps that then inject the grout uniformly throughout the depth of the layer of RCC. Although some results have been promising by including a high dose of air entrainment in the grout, the results are more typically sporadic, with much of the air entrainment being lost by the time the mix is consolidated and sets. Tests and experience, however, have shown that the traditional amounts of air entrainment necessary for good freeze–thaw resistance are not typically required for RCC. Air entrainment is still essential, but a good-quality paste with just a few percent of entrained air has shown itself to be very effective at times (Schrader et al., 2003b).

20.4 Material Properties

20.4.1 Density and Air Content

The density and natural air void content (not entrained air) of RCC depend on the specific gravity of the aggregate, the grading, the moisture content, and the degree of compaction. Fully compacted RCC will typically have less air content and less water than conventional concrete, so its density will be slightly higher. Because RCC has been made with aggregates having a wide range of specific gravities, the specific densities of compacted RCC at different projects varies greatly from about 2.1 to 2.9. Fully compacted RCC with reasonable mixture proportions typically has an air content on the order of 0.5 to 1.5%. Specifications commonly require that field densities must obtain an average of 98% of the maximum practical achievable density (MPAD) at each test location, which is often considered to be 97% of the theoretical air-free (TAF) density, providing that no density at any level within a lift of RCC is less than about 93% of the TAF density. The average density is based on measurements taken at the top, middle, and bottom thirds of the lift. Air contents can be obtained in the laboratory using the pressure method for material compacted by tamping or by the vibrating table method, whichever is appropriate for the mixture consistency. Some of the first RCC projects required greater densities than suggested above, with the thought that densities representing 98 to 100% of the TAF would result in significant increases in strength. This is not correct. Unfortunately, some older specifications and concepts continue to be copied. As shown in Figure 20.19, it is important to achieve a reasonably well-compacted mix with a density of at least 95 to 96% of the TAF, but greater densities provide essentially no increase in strength. Excessive compactive effort can actually be harmful. Excessive compaction can cause a reduction in strength if it begins to break the aggregate particles, and, as with most gravel and sands, overcompaction of RCC can also begin to loosen the material and reduce density.

20.4.2 Coefficient of Thermal Expansion

The coefficient of thermal expansion of RCC tends to be slightly higher than the thermal expansion coefficient of the aggregate and slightly less than that for a conventional concrete made with the same aggregate but more cement paste. Because of the wide range of aggregate materials that can be used in RCC, the range of thermal expansion coefficients is much wider than would be expected for traditional concrete. Traditional concrete typically has an expansion coefficient somewhere between 4 and 8 millionths per degree Fahrenheit. Measured expansion coefficients for RCC have varied from about 3 to about 18 millionths per degree Fahrenheit.

20.4.3 Thermal Diffusivity and Conductivity

Thermal diffusivity and conductivity of RCC mixes tend to be similar to the values obtained for the aggregate by itself and similar to conventional mass concrete made with that aggregate.

20.4.4 Poisson's Ratio

Poisson's ratio for RCC tends to be similar to values for conventional mass concrete; typical values are on the order of 0.18 to 0.24, depending on the concrete age, aggregate, and strength. At very early ages and very low strengths and for mixtures with soft aggregates or very high contents of noncementitious fines, Poisson's ratio can be much higher. Under these conditions, some RCC mixes have had Poisson's ratio values on the order of 0.3 to 0.5.

20.4.5 Autogenous Volume Change

Autogenous volume change (the increase or decrease in size with no applied load or environmental change) cannot be reliably estimated in conventional mass concrete without at least some test data. This is true of RCC also, especially for mixtures that have peculiar cement, pozzolan, and aggregate. In some cases, there has been early expansion followed by a later period of contraction, or *vice versa*. Typically, the amount of change is minimal and of little consequence, but the potential for expansion or contraction can be important to large mass structures and should be investigated for large projects and for dam projects that use unusual materials. Autogenous volume changes should be considered when determining strain and creep properties and when performing a cracking analysis of large RCC structures.

20.4.6 Freeze–Thaw Resistance

(See also Section 20.3.6.) Resistance to freezing and thawing of non-air-entrained RCC subjected to natural exposure has usually been reasonably good, even when these materials had performed badly in laboratory tests. Examples include projects such as Winchester and Willow Creek Dams, which have unformed and uncompacted downstream faces of exposed RCC with cementitious material contents for the exposed face of 175 and 255 lb/yd³, respectively. Monksville Dam is another project with an unformed downstream face but with a cement content of only 105 lb/yd³ (no fly ash or pozzolan). Initially it performed well in freeze–thaw exposure, but after many years it began to show areas of deterioration. Some of this was localized, and attributable to issues during construction, but overall the severe environment has had an effect. Each of these projects receives almost daily cycles of freezing and thawing during much of the winter. Monksville and Willow Creek also have saturation from lift-joint seepage. After more than 25 years, Willow Creek and Winchester have not shown any significant change in the downstream face. Other projects, such as Middle Fork, located in severe climates where temperatures can reach –40°F and that used about 1 ft of conventional concrete facing, have also shown no distress.

Based on test data and observations, the following typical deterioration rates have been developed by the author. These estimates are for cementitious material contents in the range of 85 to 250 lb/yd³. The deterioration rate for unformed and uncompacted surfaces subjected to freeze–thaw cycles that penetrate about 1 inch is 1 inch of erosion per 100 to 250 cycles of freeze–thaw. Compacted interior RCC is estimated to deteriorate at about 1000 to 2000 cycles per inch of erosion.

As discussed in the sections on aggregates, chemical admixtures, and mix proportions, some projects have been able to achieve sufficient air entrainment to provide good freeze–thaw **durability** even in severe laboratory tests. Early RCC studies indicated that this might be possible only with high-cementitious-content mixtures with very wet consistencies; however, some lower and medium cementitious content mixtures with a relatively dry consistency have also achieved adequate air entrainment and durability using some admixtures. Synthetic air-entraining admixtures seem to offer the best promise, but traditional admixtures have also worked at times. A clear understanding of which admixture will work best is not achieved until after comprehensive testing for each RCC mix and set of materials. A recent example is the set of initial mix studies for the Tongue River project, which is exposed to temperatures ranging from about -40°F to $+120^{\circ}\text{F}$. Another recent series of interesting tests was done for the proposed Nordlingaalda Dam in Iceland, where very good freeze–thaw resistance was achieved with a normal air-entraining admixture and medium cementitious content at a relatively low entrained-air content (Schrader et al., 2003b).

20.4.7 Cavitation and Erosion Resistance

Cavitation and erosion resistance of RCC have been surprisingly good, and a historical summary has been published (Schrader and Stefanakos, 1995). Very early evaluations of erosion resistance, including full-scale tests at velocities on the order of about 100 ft/sec, were documented by the U.S. Army Corps of Engineers (1981). Based on available data, including two high-velocity and high-head, full-scale trials for a limited duration as well as laboratory and other tests, cavitation and erosion rates have been developed and used with caution to justify exposed RCC spillway surfaces. Assuming good-quality mixtures with cementitious-material contents on the order of 170 to 300 lb/yd³, an erosion rate of 0.002 lb per square foot of surface per hour of exposure has been extrapolated for a rolled surface and 0.05 lb per square foot of surface per hour of exposure for a rough surface. Field experience confirms that these numbers are either reasonable or conservative.

20.4.8 Compressive Strength

The compressive strength of RCC depends on a variety of factors, including the aggregate, quantity and quality of fines, quantity and quality of cementitious material, degree of compaction, and moisture content. The efficiency, or strength per pound of cement in a cubic yard of RCC, has been discussed in Section 20.3. The wide range of strengths that has been experienced with different RCC mixes having different aggregate, cements, and pozzolans was shown in Figure 20.14. Section 20.3 also included general information about the wide disparity of pozzolan (including fly ash) performance in RCC and the effect of moisture on compressive strength. The relationship between compressive strength and density or air voids content was discussed earlier in Section 20.4.1.

Care must be used when reviewing RCC literature that is based only on one set of site-specific aggregates, pozzolans, mixture proportions, moisture contents, and gradations. Publications occasionally offer misleading global statements about RCC strength when, in fact, the experience used as a basis for those statements has included only one project, one set of materials, and one type of RCC mixture. Because of the wide range of materials and mixture proportions that can be used in RCC, it is very difficult to develop global or general statements or rules about RCC strength relationships. Figure 20.11 through Figure 20.14 show examples of the wide range of strengths, different rates of strength gain, and the wide range in strength performance that can occur with RCC mixes containing fly ash or other pozzolans.

Traditional thinking would limit the amount of fines (material passing the No. 200 sieve) in the aggregate to very small amounts, based on the accepted traditional concept that clean washed aggregates with no fines are best. However, as discussed in Section 20.3, natural or manmade fines are essential in low cementitious RCC mixtures to provide adequate paste and to fill void spaces for control of segregation and for compaction. Nonplastic fines typically increase the strength of low-cementitious-content mixtures. The reasons for this are not entirely clear. In some cases, it is probable that the fines are providing

FIGURE 20.20 Effect of fines on strength (Willow Creek Dam).

FIGURE 20.21 Effect of fines on compressive strength (Agos Dam).

some degree of pozzolanic strength gain, but it also appears that mechanical benefit is also being provided. Because the fines have substantial surface area and they are used primarily in low cementitious content mixes, the traditional thought that sufficient cementitious material is needed to coat all of the aggregate surfaces obviously does not apply to RCC.

Figure 20.20 shows a case where the addition of fines caused an increase in strength in a medium cementitious content mix. In this situation, the optimum fines content was about 5 to 6%. A slight increase in fines to about 8% resulted in minimal additional strength. At even higher fines contents, the strength could be expected to decrease. The fines were a natural silt with very little plasticity. Figure 20.20 also shows much lower strengths at every age when the aggregate was washed to eliminate all fines, screened to an ideal traditional gradation, and used to make low-slump conventional concrete. Additionally, it shows the strength achieved when the dirty RCC aggregate was washed and sorted to an ideal conventional aggregate gradation. The mix made with this gradation was an excellent quality 2-in. slump mix with a water-reducing admixture. At all ages, the strength of the conventional concrete was substantially less than the RCC concrete made with the same basic aggregate without the expensive washing.

Figure 20.21 shows another project demonstrating nontypical behavior where an increased fines content of a low cementitious content mix caused a slight reduction in strength. The only way this was

FIGURE 20.22 Compressive strengths (Salt Lick Dam). (Data courtesy of Gannett Fleming Engineers, Harrisburg, PA.)

FIGURE 20.23 Strength vs. time (Stagecoach Dam).

detected was by tests. In this case, the fines were siliceous and expected to add substantially to, rather than decrease, the strength. Figure 20.22 shows very good strength gain for a mixture that was used in an application where durability and traditional strength levels of about 4000 psi were important. This was achieved with only 270 lb of cement per cubic yard (135 lb of cement and 135 lb of fly ash). The aggregate was limestone, including the beneficial rock dust which, in the case of limestone, was expected to react somewhat with the siliceous fly ash. Figure 20.23 shows the benefit of fly ash in a low-strength mass RCC made with lower quality aggregates at Stagecoach Dam. In this case, evaluation of the comparative mixtures at ages up to 28 days indicated that fly ash was not beneficial; however, after 28 days the ash performed extremely well, ultimately achieving a strength greater than the mix made with cementitious material that was 100% Portland cement with no ash. In this case, the aggregates were lower quality and the efficiency of the cementitious material was relatively low by RCC standards.

Although Figure 20.22 and Figure 20.23 suggest that fly ash is very beneficial in RCC and can even be better than adding more Portland cement, this is not always the case. Figure 20.21 and Figure 20.24 show mixtures where adding fly ash increased the cost and complexity of the mix while doing essentially nothing for strength. Figure 20.21 shows that when a mix with 202 lb of cement per cubic yard used fly ash for 25% of the cementitious material the strength was reduced by about 25% at all ages, including

FIGURE 20.24 Strength vs. time (Willow Creek Dam).

the long-term ages up to 1 year. Figure 20.24 indicates that a mix with 175 lb of cement per cubic yard had no significant change in strength when 80 lb of ash per cubic yard was added. In this case, adding silty fines to the mix was found to have the same or better effect as adding fly ash. Figure 20.22 and Figure 20.24 show RCC mixes that achieved relatively high strengths on the order of 4000 and 6000 psi, respectively. This is comparable to very good quality traditional concrete, but the strength was achieved with cementitious contents that are about half that used in traditional concrete. Figure 20.20 through Figure 20.24 represent a wide variety of RCC mixtures, with different aggregate types and gradations, different cementitious and fly ash contents, and different maximum aggregate sizes. In all the examples, the individual data points have been plotted to show that, although the strength gain trends can be different from mix to mix, the strength gain trend for any given RCC mix plots vary predictably with an incredibly small amount of data dispersion. RCC is a reliable engineering material with predictable and dependable properties once a mix design program has been undertaken.

Figure 20.20 through Figure 20.24 plot strength vs. time. Another very useful way to present the data is by plotting strength vs. cementitious content, with different lines representing different ages, as shown in Figure 20.25. From the family of curves shown, the required cementitious content can then be selected

FIGURE 20.25 Compression vs. cement content.

FIGURE 20.26 Split tension vs. time for different cement contents (Big Haynes).

to achieve any strength at any age. The shape of these curves is of particular interest. Figure 20.25 shows a generally linear relationship between strength and cementitious content from 0 to 230 lb of cement per cubic yard; however, other RCC mixes have shown no significant strength gain beyond a certain cementitious content. In other cases, no significant strength was achieved until some minimal amount of cementitious material was used.

The strength data and charts are for projects that range from the start of RCC dams 30 years ago to projects just now being built. Throughout the history of RCC to the present, some projects simply have not benefited from using pozzolan but others have. By relying on an all-encompassing, open-minded approach to mix design studies on both high and low cementitious contents with both high and low pozzolan contents, a project manager can properly evaluate whether or not it is advisable to use pozzolan and how much to use (Schrader, 2004).

20.4.9 Tensile Strength

As with compressive strength, the tensile strength of RCC can vary greatly from mixture to mixture. Cementitious material content is a principal influencing factor, but moisture content and aggregates are also important. Higher cementitious material contents, lower moisture, and crushed coarse aggregates tend to increase tensile strength; however, the tensile *strain* capacity, discussed below, may be more important than the tensile *strength*. A highly deformable mixture with a low elastic modulus can be more desirable than a stronger mixture that is much more brittle and cracks earlier under the same amount of deformation.

The Brazilian split-cylinder test (ASTM C 496) is a simple and economical indirect method of obtaining an indication of the direct tensile strength of concrete. It is frequently used for RCC, but care must be taken when deriving the probable direct tensile strength from indirect split-tension results. This applies to traditional concrete as well, but it is more important for RCC where the relationship of direct to indirect strength can vary from project to project as well as within the range of compressive strengths that might be considered for a particular project. Figure 20.26 and Figure 20.27 show examples of the development of split tensile strength with time for a crushed gneiss aggregate with and without fly ash. The mix designations used in the figures indicate the total amount of cement plus fly ash (in pounds per cubic yard), followed by the percentage of cementitious material that is fly ash, followed by the moisture content as a percentage of the full mix.

FIGURE 20.27 Split tension vs. percent fly ash (Big Haynes).

The split tensile strength of RCC mixtures with higher cementitious material contents and higher compressive strengths is typically a lower percentage of the compressive strength than what occurs with low-strength mixtures. Some examples of the ratio of split tension to compression strength for various mixes and tests at different projects are 4 to 7% for Upper Stillwater, 7 to 12% for Willow Creek, 9 to 13% for Monksville, 10 to 18%, 13% for Burnett (Paradise), 10 to 18% for Uruguay-I, 12 to 17% for Concepcion, 14 to 15% for Mujib, and 13 to 19% for Middle Fork. These have been listed in order from the highest to lowest average strength.

When converting split tensile strengths to direct tensile strengths, a factor should be taken into account based on the compressive strength. Figure 20.28 shows this factor as a function of the logarithm of the compressive strength (Schrader, 1995b). The factor is almost the same when converting from flexural strengths of beams to direct tensile strength and when converting from split tensile strengths to direct tensile strengths. The factor has recently been updated with additional test data (Schrader et al., 2003a). The factor for a particular compressive strength is multiplied by the split-cylinder strength to obtain the derived direct tensile strength.

FIGURE 20.28 Tensile strength conversion.

FIGURE 20.29 Derived direct tension vs. compression (Big Haynes).

For metric units in mega-pascals, the updated conversion is:

$$\text{Direct tensile strength} = [0.3 \log(10 \times \text{compressive strength})] \times (\text{split tensile strength})$$

For units in PSI the updated conversion is:

$$\text{Direct tensile strength} = [0.2 \log(\text{compressive strength})] \times (\text{split tensile strength})$$

When all of the adjusting factors are taken into consideration, the final ratio of direct tensile strength to compressive strength typically is nearly a direct linear relationship, as indicated in Figure 20.29.

20.4.10 Modulus of Elasticity

The modulus of elasticity and creep for RCC can have an extraordinary range of values. Mixtures with large amounts of cementitious materials and mixtures made by the water/cementitious materials ratio approach to mixture proportioning usually produce long-term values for the static and sustained elastic modulus and creep similar to conventional mass concrete—namely, modulus values on the order of 3 to 4 million psi and creep values on the order 0.02 to 0.05 ln (time) for loading ages of about 28 to 90 days. Mixtures made with very high pozzolan contents can usually be expected to have lower early-age values of static modulus but higher later-age values.

Low-cementitious-content mixtures can have very low elastic modulus values and high creep rates. The decrease in modulus and increase in creep tends to be exponentially proportional to decreases in strength below about 1500 psi. Each incremental decrease in cement content has much more effect than the previous incremental decrease, but each mixture and aggregate can perform differently. Static modulus values on the order of 0.1 to 1.5 million psi are reasonable for cementitious material contents on the order of 100 to 125 lb/yd³ at ages of 3 to 90 days. Corresponding ultimate values could be on the order of 0.8 to 2.5 million psi. At Burton Gorge Dam, ultimate elastic moduli were on the order of only 0.15 to 0.30 million psi. This was a quality designed into the mixture. It is attributed mostly to the gradation and use of what might normally be considered lower quality aggregates. A deformable concrete was desired to avoid thermal stress and because the foundation condition had a low and varying mass modulus that could not be accurately predefined. Figure 20.30 shows the typical range of the modulus of elasticity for traditional concrete and extreme values that have occurred with RCC. Although it is an extreme example, it is important to note the substantial increase of modulus (increased stiffness) at later ages for the Agos mix studies. This is attributed to the pozzolanic activity of the added fly ash, plus some

FIGURE 20.30 Modulus of elasticity, typical range.

suspected pozzolanic activity from the natural fines. In this case, a similar increase in strength did not develop; that is, the stiffness increased substantially with time while strength increased at a slower rate. The same occurred for some mixes at the La Miel I project. In both cases, the addition of fly ash caused no noticeable strength gain, although it did cause the RCC to become much more brittle; consequently, the mix in these cases was more susceptible to cracking due to pozzolans.

Figure 20.31 shows the derivation of a new and useful value referred to as the **ultimate modulus**, which is the slope of the secant drawn from the origin to the average peak compressive strength of companion cylinders at failure (Schrader, 1995b; Schrader and Rashed, 2002). It is clear in this typical example that it takes much more deformation and substantial energy to cause the lower strength RCC mixture to fail compared to the higher strength mixture. The mixes were made with identical aggregates and moisture contents and the same source of cement. The only difference was the increased cement content from 100 lb/yd³ to 225 lb/yd³. A lower ultimate modulus is associated with more deformation before cracking.

FIGURE 20.31 Modulus of elasticity, elastic and ultimate.

FIGURE 20.32 Elastic modulus at 25% of ultimate load vs. compression.

This is highly desired in a mass structure but may be a detriment in more traditional structures such as bridges. In a cracking analysis of mass concrete, it is the ultimate condition that is critical and that should be studied, not just the elastic condition. As the mix becomes stronger, the elastic and ultimate modulus come closer to the same value, so it is not as important with higher strength mixtures. With lower strength mixtures that are typical of mass placements, using the elastic modulus alone in the cracking analysis can be an extraordinarily conservative approach. The ultimate modulus in compression is a reasonable indicator of the ultimate modulus in tension (Schrader and Rashed, 2002). Figure 20.32 shows the relationship between elastic modulus and compressive strength for a typical RCC mixture with reasonable quality aggregates and about 5% fines. Figure 20.33 shows the relationship between ultimate modulus and compression for the same RCC.

FIGURE 20.33 Ultimate modulus at 100% of ultimate load vs. compression.

FIGURE 20.34 Specific creep.

20.4.11 Creep

Creep can be thought of in two ways. First, it is the increase in deflection or strain over time due to a sustained load. Second, it is the relaxation of stress over time while maintaining constant deformation or strain. A very high creep rate with associated dramatic reductions in stress over time is possible with low-cementitious-content RCC mixtures. When combined with the initial elastic modulus, creep reduces the **sustained modulus** that is effective over a long time period, thereby improving the crack resistance of massive placements subjected to thermal stresses (Tatro and Schrader, 1992). Figure 20.34 shows the relationship between strength at the time of initial loading and creep. The amount of creep over a selected period of time is the creep factor $F(k)$ multiplied by the natural log of the age in days plus 1 day.

20.4.12 Tensile-Strain Capacity and Toughness

Tensile-strain capacity is related to the modulus of elasticity and tensile strength. Fast-load strain capacities (maximum deformability without apparent cracking) are obtained when the load is applied over a time span of seconds or minutes. However, in dams and other massive structures, the primary concern is for slow-load strain capacity, where the strain due to external forces and internal thermal cooling develops over a long period of time. Because of creep, a dam can usually undergo more deformation without cracking if it is slowly stretched vs. when it is suddenly deformed; therefore, mixtures, with a low elastic modulus during the period of loading and a high creep rate, such as occurs with low-cementitious-material-content RCC mixtures, can have good slow-load strain properties despite low strengths.

Typical slow-load strain capacities for RCC dam mixtures are on the order of about 90 to 150 microstrain ($\text{in./in.} \times 10^{-6}$), but values outside of this range are possible. Each mixture should be evaluated, if not by direct slow-load strain capacity tests then indirectly by extrapolation from static modulus of elasticity and creep studies that can be combined to get a sustained modulus value. The tensile strength divided by the sustained modulus will provide a dependable estimate of the slow-load strain capacity over the period of time in question (Ditchy and Schrader, 1988; Tatro and Schrader, 1992; USACE, 1997). The problem with extrapolation is that it assumes that the creep rate in tension will be similar to compression (as tested). This can be conservative, especially for mixtures that contain a relatively large amount of coarse aggregate. Aggregate-to-aggregate contact can decrease creep in compression.

FIGURE 20.35 Tensile-strain capacity and RCC examples.

Because of the low modulus associated with RCC mixtures having lower strength and lower cementitious contents, decreasing rather than increasing the cementitious content and strength of a mixture can actually increase rather than decrease the tensile-strain capacity. This occurs when a decrease in cementitious content results in a greater decrease in modulus than the associated decrease in tensile strength. The ultimate example is the mix that has no cementitious content and insufficient stiffness to define a crack. Obviously, this would also result in an RCC with virtually no strength. Adequate cementitious material is necessary to resist the applied loads, but additional strength does not necessarily mean more crack resistance. Additional strength could result in more cracking. Figure 20.35 is an example of tensile-strain capacity and the tensile modulus of elasticity for mixes with different strengths. The mix numbers next to each tensile stress-strain curve represent the mixture that was used; the first number is the cementitious content, the second number is the percentage of fly ash or pozzolan, and the third number is the moisture content of the fresh mix. In this case, the mix with a cementitious content of 405 lb/yd³ (with 33% of that being fly ash) had a tensile-strain capacity of about 90 millionths of an inch per inch of length. The mix with only 160 lb/yd³ of cementitious material also used a very poor-quality aggregate. Its tensile strength was a low 55 psi, but its tensile-strain capacity was very high at about 340 millionths. The structure built with this mix, Concepcion Dam, has been in service for over 8 years with no cracking or distress. Because of the strain capacity of the mix, it was constructed with no cooling to control thermal stresses and contraction.

A very important consideration with lower-strength RCC mixtures is their demonstrated tensile toughness. This is related to ultimate tensile-strain capacity. Substantial toughness is not apparent in higher strength RCC or most conventional concrete. The indication of substantial toughness in lower strength mixtures is a relatively new discovery being demonstrated with time, experience, and assemblage of data. Such toughness can contribute to considerable benefits in dam performance and should be considered as an influencing factor in new dam designs and analyses. Eventually, it may lead to more efficient and economical dams that consider fracture toughness in the design. Toughness can be thought of as the ability to absorb energy. Another way to consider it is as a material property that results in the need for substantial energy to be added to cause the concrete to fail after it has been stressed beyond its elastic range.

20.4.13 Adiabatic Temperature Rise

Major decisions concerning schedule, cost, construction controls, and cracking potential are based on the expected adiabatic temperature rise of the RCC. This should be determined by careful testing using large samples and an experienced laboratory for any large or critical project. Determinations of adiabatic temperature rise based on calculations from the **heat of hydration** of the cementitious materials and the

properties of the aggregates have been reasonably accurate for some RCC mixes and quite inaccurate for others. There does not appear to be any good indicator of when they will be reliable. The only way to ensure the proper knowledge of potential peak temperatures as well as the rate of temperature rise for RCC is by proper testing of the full mixture with large samples that have a volume on the order of about 10 ft³. Companion tests of the heat of hydration of the cement by itself and the heat of hydration of the cement with pozzolan (if used) are useful for later reference.

A review of adiabatic rise for various RCC projects, typically using Type II moderate-heat cement, shows ranges (in degrees Fahrenheit rise per pound of cementitious material in each cubic yard of RCC) of 0.0 to 0.10°F at 1 day, 0.09 to 0.18°F at 7 day, and 0.13 to 0.21°F at 28 day. The adiabatic rise for RCC mixtures, especially those with large proportions of fly ash should also be determined through later ages of 56 to 90 days or more. The assumption that RCC, and other mass concrete, does not produce heat past an age of 7 or 28 days is simply not correct. Exothermic chemical reactions from hydration continue long term, even through one year. The rate of heat generation decreases with time, but it is still there. Also, the thought that fly ash does not produce heat simply is not correct. Depending on its chemistry and reaction with the cement and aggregate fines, this may be a very small amount of heat, or it may be substantial. Proper detailed tests with site-specific materials are necessary to accurately establish just how much heat is produced and when it is produced. Mixtures with lower cement contents tend to produce higher temperature rises per unit of cement. This is even more evident if pozzolan is included.

20.4.14 Thermal Stress Coefficients

Thermal stress coefficients establish how much internal tensile stress will develop in a given mixture for each degree of temperature drop over a specified period of time, assuming the RCC is restrained. RCC can have a broad range of values depending on the mixture proportions and aggregate. It is influenced by creep, coefficient of thermal expansion, and the elastic modulus. Stronger mixtures typically have much higher stress coefficients. For a time period of 28 to 365 days, typical values for low-strength mixtures (800 to 1800 psi) with low cementitious material contents are on the order of 4 to 6 psi/°F. Higher strength mixtures (2000 to 4000 psi) have stress coefficients on the order of 8 to 14 psi/°F.

20.4.15 Shear Strength and Lift-Joint Quality

The shear strength of an unjointed RCC mass, of RCC containing joints with strengths similar to the mass and of RCC with the principal load normal to the joints will generally be 10 to 20% of the compressive strength for strengths in excess of 2500 psi, about 15 to 25% for strengths on the order of 2000 psi, and about 25 to 30% for strengths on the order of 1000 psi. Lift joints, or the layer-to-layer interfaces, are the weakest part of RCC structures. Special treatments such as a bedding or mortar mix or high cementitious content mixtures can improve this problem considerably, but these techniques are expensive and time consuming. Lift-joint quality as it relates to shear strength is elaborated below; lift-joint quality as it relates to watertightness is discussed in Section 20.4.16.

The strength of RCC lift joints is primarily dependent on the consistency of the fresh mixture, aggregate characteristics, degree of compaction at the lift surface, cementitious-material content, maturity of the lift surface when it is covered with the next lift, effectiveness of retarding admixtures, condition of the lift surface, and lift-surface treatments. A detailed procedure for assessing lift-joint quality in the field, taking into account the many factors that affect the probable lift-joint strength, has been developed (Schrader, 1995c,d, 1999a). On the basis of clearly defined criteria, the procedure establishes a numerical value (plus or minus) for each of the following factors that influence the *in situ* shear strength: surface segregation, rain, cure, maturity, surface tightness and condition, surface flatness, method of RCC delivery, and miscellaneous factors. The sum of the numerical points assigned in each category is referred to as the **lift-joint quality index (LJQI)**. The basis of design corresponds to a LJQI of 0.0. Any positive value implies a slight improvement in quality above the basis of design. A negative value indicates a quality less than the basis of design. A graph provided with the procedure indicates the percentage of the design values for **cohesion** and the percentage of the design value for friction that is associated with

various values for the LJQI (Schrader, 1995c,d, Schrader 1999a). As a matter of inspection and field control, the contractor may be penalized for slightly negative but tolerable LJQI work, with a cut-off point at about -4 , below which the structure would not perform acceptably and the work is not accepted.

A wide range of possible RCC joint strengths exists, depending on the mix and the above variables, with extremes ranging from about 0 to 400 psi for cohesion and 30 to 60° for friction angles; for example, one early summary of strengths for 35 tests that included 5 projects, 10 mixtures, 8 joint conditions, and 5 aggregate types demonstrated an average cohesion of 155 psi and a friction angle of 50° (Schrader, 1986). Each project should be carefully examined and preferably tested to determine the shear capacity of its joints. Well-proportioned, dry, low-cementitious-content mixtures with reasonable aggregates and construction controls can be expected to produce friction angles on the order of 45°, with cohesion values on the order of 40 to 110 psi. High cementitious content wetter mixtures typically have similar or slightly lower friction angles and cohesion values that may range from about 110 to 300 psi. The reduction of friction with increasing cementitious contents is usually minimal, but it tends to routinely occur when tested. The residual friction after sliding also seems to decrease for higher cementitious content mixes (Schrader, 1995c,d, 1999a, 2003d). The reason appears to be that the fine paste has less friction than the aggregate that it is replacing.

Substantial testing of lift joints reported for a variety of projects provides useful data for those specific mixtures and conditions (ACI Committee 207.5R, 1999; Boggs and Richardson, 1985; Cannon, 1985; Dolen and Tayabji, 1988; Dunstan, 1981; Gaekel and Schrader, 1992; Hansen and Reinhardt, 1991; McLean and Pierce, 1988; Oberholtzer et al., 1988; Schrader, 1982a,b, 1984, 1986, 1994, 1995b,c,d, 1999a, 2003d; Schrader and Rizzo, 2003; Tayabji and Okamoto, 1987). The most comprehensive series of tests on full-scale samples, with emphasis on shear resistance of cracked or debonded lift joints and residual strength after sliding, was done for the Saluda Dam (Schrader and Rizzo, 2003). Care must be exercised not to use one publication or one set of results that is based on one set of conditions at one project as an absolute basis for what will occur at another project. A general idea can be developed based on a compilation of information from other projects and a knowledge of the mixture and materials proposed for a new project, but absolute values should come from testing the specific mixture and conditions in question.

Every job may have its own peculiarities, but generalized observations typical of most RCC follow: Shear strength increases with age. A wetter consistency at the same cementitious material content can slightly decrease the cohesion. Higher cementitious content mixtures achieve higher potential cohesion, but the friction is essentially unaffected. Lift-joint exposure maturity (exposure time \times surface temperature) is a major influencing factor in lift-joint quality or strength. Figure 20.36 shows the general trend

Typical trends (approximately 25% ash)
Not retarded, Type I joint

FIGURE 20.36 Friction or cohesion, effect of age.

FIGURE 20.37 Friction or cohesion, effect of joint maturity.

FIGURE 20.38 Miel I lift-joint cohesion vs. cement.

or effect of age on cohesion and friction for mixes with both high and low contents of cement plus pozzolan. Figure 20.37 shows the general trend for lift-joint maturity on cohesion and friction for mixes with both high and low cement and pozzolan content. These figures are intended to show typical or general trends; they should not be used as a basis for design without further consideration for the peculiarities of the RCC specific to each project.

Figure 20.38 is an example of site-specific tests for the Miel I project. The effect of cement content, maturity, admixture, and bedding mix on cohesion is clearly defined for these materials. The mix used only cement, with no fly ash or pozzolan, but it did contain approximately 6% aggregate fines. The bedding mix consisted of a 3/4-in.-thick layer of high-slump traditional concrete with about 45% sand and a high cement content. It was spread just prior to placing the RCC, and the RCC was then compacted over the bedding. Figure 20.39 shows that the friction angle is essentially independent of

FIGURE 20.39 Miel I lift-joint friction vs. cement.

FIGURE 20.40 Miel I lift-joint shear.

maturity, cement content, admixtures, and bedding. It is almost entirely a function of the physical aggregate characteristics.

Figure 20.40 shows a typical plot of total shear stress resistance as a function of the confining stress applied normal to the lift-joint surface. These tests were performed on large blocks saw-cut from the full RCC mix. The mix contained 169 lb/yd³ of cement with no fly ash or pozzolan. It had a relatively dry consistency with 4.8% moisture and 6.2% aggregate fines. A surprising result, similar to those of full-scale tests at other projects with other materials, is that allowing the surface to dry just prior to placing the next layer of RCC had virtually no negative effect on the joint strength. This is contrary to traditional practice for conventional concrete. In the field, allowing the surface to dry just prior to placing the next layer allows efficient and very effective cleaning by blowing the surface with compressed air, thereby achieving an even better joint quality.

20.4.16 Seepage, Permeability, and Watertightness

At the time of early RCC projects, confusion developed concerning permeability and seepage in RCC dams because they were sometimes discussed or presented and compared using data that had a very different basis. Any one, or any combination, of the following was used: pressure tests and water-loss results from drill holes in dams; recordings of seepage collected from drain holes drilled into dams that may or may not have included holes that extended into the foundation or abutments; recordings of discharges from galleries or stilling basins that may have included water from any combination of sources such as foundation drains, drilled drains in the dam, cracks, monolith joints, local runoff, drains in the RCC, and water from construction activities; tests of cores that may or may not have contained joints that may or may not be oriented with or against the flow path; and permeability tests of laboratory prepared cylinders.

Another problem in reporting seepage data is the lack of a full grasp of the details of internal drains, their construction, their purpose, and how they function; for example, the design for the Urugua-I Dam originally had a grid of face drains behind the upstream membrane so seepage through the membrane could be detected and isolated if it occurred. Because of the 100% effectiveness of liner systems at other dams and confidence that the liner would have no seepage, this was deleted from the work. Only a single drain line was installed. It was located behind the membrane, just above the foundation. Seepage from this drain has been reported as being due to membrane seepage when, in the opinion of the designers and those who were responsible for construction, the seepage is primarily due to two other causes and not the membrane. One cause is poor detail where the membrane is connected to the foundation; water comes under the foundation contact and up behind the membrane to the drain. The other cause is seepage through a portion of the abutment that had questionable grouting; water probably came into the abutment and then traveled to the dam, where some of it migrated upstream to the drain line. When seepage is present, it typically diminishes naturally with time for both conventional concrete and RCC dams. The reduction is especially dramatic with low-cementitious-content RCC dams, where seepage is primarily along lift joints. Typical reductions are on the order of about 85 to 95% within about 1 to 2 years.

Unlike low-cementitious-content RCC, which typically experiences initial seepage along lift joints that do not have special treatment, high-cementitious-content RCC behaves similarly to conventional concrete dams, which typically have negligible seepage along the lift joints. As is the case, for example, with Dworshak Dam (conventional mass concrete) and Upper Stillwater Dam (high-cementitious-content RCC), watertightness problems with these types of dams are more related to leaking monolith joints or leaking cracks. Water loss occurs as high flows or leakage concentrations at fewer isolated locations in high-cementitious-content concrete dams, whereas in the lean RCC dams (without watertight facings or special lift treatment) the unit seepage is smaller but the area of seepage is greater. Two years after their respective reservoirs were raised, leakage through one of the cracks at the very high-cementitious-content Upper Stillwater Dam was greater than all of the seepage from all sources, including foundation drains, local runoff, and lift joints at the very low-cementitious-content Willow Creek Dam (it has no monolith joints or through cracks). This is not to say that all high-cementitious-content RCC dams will have cracks and joint seepage nor that all low-cementitious-content RCC dams will have seepage of lift joints. It is meant to point out general differences and where the emphasis should be placed during design for seepage control with different types of mixtures.

Some projects have been designed to allow seepage and let it pass through the structure without being collected or drained away. Seepage in these projects was the most sensible, economical, and appropriate design. Seepage was not a result of a failed design. On the contrary, the design worked. Going back to one of the first RCC dams, the U.S. Army Corps of Engineers' *Willow Creek Design Memorandum* (USACE, 1981) included a discussion of seepage that could be initially anticipated. Performance of the dam has been almost exactly as predicted. The section or mass of the dam was increased as part of the design to offset uplift pressures along lift joints that were allowed to seep without benefit of an internal uplift reduction drain system. The seepage has reduced naturally over time to about 10% of the initial value. Extensive coring soon after construction and again after years of steady seepage has shown no detrimental

FIGURE 20.41 Sample permeabilities.

effects. This includes tests of joint strength (tension, cohesion, and friction), compression, density, tension, and appearance despite aggressive reservoir water.

Figure 20.41 illustrates essentially no change in RCC permeability (excluding joints) with changing cementitious contents, including very low cementitious contents of only 100 lb/yd³. The data represent the average permeability values primarily for test samples of RCC actually used on completed dams. For comparison, the figure also shows sample permeability values from tests of conventional mass concrete. The results of the latter are similar to RCC. All of the mixtures have permeability values suitable for dam construction. Table 20.9 shows specific average test results for various RCC mixtures listed in ascending order of cementitious-material content. It is clear from comparing the cementitious-material content to the permeability values that no defined relationship exists between cementitious-material content and permeability within the range of 100 to 450 lb/yd³. It is also clear from the table that no defined relationship exists between permeability and the proportion of cementitious material that is pozzolan.

Confusion about seepage can be easily clarified and summarized as follows. Properly designed RCC mixtures all have low permeabilities that are similar to conventional mass concrete, about 1 to 10×10^9

TABLE 20.9 Roller-Compacted Concrete Permeability: Average of Cores

Project	Cement + Pozzolan (lb/yd ³)	Permeability (cm/sec $\times 10^{-9}$)
Urugua-I	101 + 0 = 101	1.4
Willow	80 + 32 = 112	0.3
Zintel	125 + 0 = 125	3.3
Lost Creek	94 + 76 = 170	11.3
Elk Creek	118 + 56 = 174	0.8
Willow	175 + 0 = 175	1.5
Cuchillo Negro	130 + 100 = 230	0.3
Lost Creek	234 + 0 = 234	3.9
Willow	175 + 80 = 255	0.3
Lost Creek	120 + 140 = 260	1.3
Zintel	300 + 0 = 300	1.1
Willow	315 + 135 = 450	1.0
WES	517 + 0 = 517	0.3

cm/sec, regardless of cement and pozzolan content (this statement applies to the compacted mass without joints). A key aspect of properly designed RCC mixtures is that they contain at least 20% by volume of material finer than 75 μm . This includes all materials (water, small air bubbles, pozzolan, admixtures, slag, aggregate fines, and cement). If a low-cementitious-content RCC is made without adding fines to keep the paste volume greater than about 20%, the mixture is poorly proportioned and greater permeability can be expected.

Along with these strong statements about the permeability of unjointed RCC mass, a companion statement is also necessary. If special precautions (such as bedding mixture, upstream membrane, or fast lift placement) are not used, low-cementitious-content RCC dams with a dry consistency will have lift joints that seep. The joints can still achieve good friction and cohesion properties, reasonable tensile strengths, and even look tight, but they will seep. The total quantity of seepage through the joints may be low, but the unit seepage rate along the thin lift joint can be on the order of 1×10^{-3} cm/sec. If this seepage is allowed to penetrate through the dam instead of being intercepted by drains, it may cause uplift and cause the entire mass to look like it is seeping. In numerous applications this condition is tolerable and may be the best overall design, but in other applications special precautions to control seepage or a different type of design are appropriate. If a higher cementitious-content mixture with a wetter consistency is used, lift-joint seepage problems will be similar to those encountered with traditional concrete.

A few clarifications are appropriate. Bedding mixture (a retarded sanded grout or high-slump small-aggregate conventional concrete) will provide watertightness if the bedding mixture extends downstream from the upstream face a distance approximately equal to at least 8% of the hydraulic height above the joint. In the process, the bedding mixture will also provide improved tensile and shear strength. This assumes that the bedding is always placed correctly. In practice, it is reasonable to expect that there will be some less-than-perfect placement of the bedding mixture in any large project; consequently, it is reasonable to assume that some lift joints may have some seepage, just as occurs with traditionally placed mass concrete or high-cementitious-content RCC. This is usually minimal; it can be picked up by drains and will reduce substantially with time. Adding to the width of bedding provides some additional protection, but because of interference with other aspects of the construction it also makes placement of the bedding and achieving good quality more difficult. If total watertightness is desired, regardless of cracks, joints, failed water stops, poor-quality lift joints, or low-cementitious-content mixtures, the impervious upstream membrane system discussed in the next section should be considered.

20.5 Design

20.5.1 General

Efficient RCC designs require balancing considerations including stability of the structure and foundation, stresses from applied loads and dead loads, thermal stresses, construction methods and rates of placement, and mixture proportions including their material properties. Because of the low cost of RCC, the wide range of material properties possible (including properties not possible with conventional concrete), and the ability to use marginal or normally unsuitable materials if necessary, the designer needs to evaluate many more possibilities than would be necessary for conventional concrete. Also, it is necessary to pay more attention to the interrelationship of design with what might otherwise be considered inconsequential decisions with regard to construction. Examples that relate to positioning supports for RCC delivery conveyors and to leveling concrete are discussed in Section 20.6.1. The designer has a more complex task, but he also has greater opportunity to save time and money for the project and maximize the use of available resources and materials.

Roller-compacted concrete has been used for a variety of mass applications. An old example is the base on which structural concrete was placed at the Bellefonte Nuclear Plant, the base on which hydroelectric power plants were constructed at the Tarbela project, and the base under a number of large spillways. Other examples of mass applications are large buttresses or supporting walls for potentially large landslides, as was done along flood channels in El Paso and as was done for the mountainside at

the Platanovryssi Dam. Still other mass applications involve erosion protection for enormous plunge pools and stilling basins that would otherwise erode from extreme water flows at both low and high velocity (Schrader and Stefanakos, 1995). The most complex massive RCC structures, and the most common applications, are dams. The remainder of this section on design concentrates on RCC dams, but much of the content applies to other massive applications such as walls and buttresses.

Foundations that are suitable for traditional concrete dams and massive structures are also suitable for RCC dams and massive structures; however, RCC can also use foundations that would normally not be considered acceptable for concrete structures. Because RCC is less expensive than conventional concrete, it is often possible to widen the base or foundation and contact area to reduce bearing pressure and provide added sliding stability. Also, by using a low-modulus RCC, irregularities in geometry and properties of the underlying materials can often be tolerated. A detailed discussion of foundation issues as they relate to RCC is beyond the scope of this chapter, but the topic is well discussed in the literature (Schrader, 2006a,b). Some examples of RCC dams on otherwise unacceptable foundations are Conception, Big Haynes, Burton Gorge, Rompepicos, and Buckhorn (Giovagnoli et al., 1991, 1992; Schrader, 1999b, 2002, 2006a,b; Schrader and Bali, 2003).

Structural design of RCC dams uses the same basic criteria and procedures used for conventional concrete dams. After the RCC has hardened in place, it is concrete. The concrete is just placed by a more efficient method than has historically been used, and it may have a design section and material properties that are outside the normal range of conventionally placed concrete structures. These attributes, plus the rapid rate of placement and the minimization or elimination of monolith joints, may require a more in-depth study of the structure. General discussions of structural design of RCC dams can be found in ACI Committee 207 (1989), Jansen (1989) and the U.S. Army Corps of Engineers (1995). Stress analysis of RCC dams, with specific example, has been published by Schrader and Rashed (2002). Recent developments have allowed for three-dimensional analyses of RCC structures that simultaneously consider time-dependent material properties, stress-dependent material properties such as the modulus, different mixes used at different locations in the structure, different times of placement for each layer or group of RCC layers, time-dependent development of thermal stresses, dead and applied loads, and seismic loads (Angulo et al., 1995).

As discussed in Section 20.4.10, RCC mixes can have substantial strain softening. The modulus (stiffness) typically decreases at high levels of loading. This phenomenon begins to occur at stresses as low as about 25% of the ultimate strength for lower cementitious content mixes, whereas it may not be seen until greater levels of load at about 75% of ultimate strength for higher cementitious content mixes. As discussed in Section 20.4.10, the reduction in stiffness can be substantial. This can be very advantageous to RCC dams, and it should be taken into account during design. It can cause localized areas of high stress, such as at the toe and heel of a dam, to redistribute much of the load to adjacent areas of lower stress, thereby reducing what would otherwise be higher peak stresses. This phenomenon can be evaluated using a software program or analysis method that allows the nonlinear stress-strain behavior associated with strain softening to be defined as part of the input. Another way to do this is by using an iterative process that first determines the stresses without strain softening. Then, based on stresses from the first iteration, the modulus is adjusted downward for areas of higher stress, using the actual secant modulus for that area and level of stress. The process is repeated. Usually about four iterations are required before the stresses and associated modulus values are balanced and the true stress distribution evolves (Schrader and Rashed, 2002).

Design should also consider probable uplift and its distribution within the dam. The main issue is uplift pressure due to seepage along lift joints. If seepage can migrate along lift joints to the downstream face but not exit or escape at the face—for example, due to a continuous conventional reinforced concrete face slab at a spillway—then allowance must be made for this trapped uplift or drains will be required under the slab to relieve the pressure.

Seepage and uplift can be reduced at the upstream face by improved lift-joint quality, either by providing a better mix with better binding characteristics or by adding a bedding mix between layers. In theory, this will prevent uplift, but in practice there still will be at least a few lift joints that allow seepage.

Unlike conventional mass concrete, which generally has about 1 lift joint per 2 m of height and special attention is given to every lift joint, RCC typically has about 7 lift joints per 2 m of height, and less time is available to ensure that each joint is carefully cleaned. Consequently, the lift joints typically receive less attention and treatment than do conventional concrete dams, there are many more joints, and there is a greater likelihood of a seeping lift joint regardless of the type of mix and treatment. In addition, even the best of conventional concrete dams usually have the occasional lift joint with seepage. Because the locations where this might occur are not known, uplift should be considered at each joint.

Uplift reduction (usually taken to be $2/3$) can be accomplished at a series of drilled drains within the dam, as is done in conventional concrete. As discussed in Section 20.5.4, a common and reliable method of providing watertightness and uplift reduction immediately at the upstream face is to use an impervious upstream synthetic membrane or a properly designed concrete facing, with integral face drains immediately behind the membrane (Scuero and Vaschetti, 2003). Until a reliable track record of field performance under many conditions was established, earlier designs considered that the membrane or facing would provide effective watertightness but that some seepage and resulting uplift could still develop. Based on excellent performance and the concept in the U.S. Army Corps of Engineers manual (USACE, 1995), which suggests that watertightness and uplift assumptions should be based on the site-specific procedure being used and its performance, recent practice has been to consider a proper membrane system to provide essentially total uplift control at the upstream face, providing that it also has a drain system to relieve pressure from any small penetrations that may develop. A conservative design approach is to allow 50 to 75% uplift reduction at the upstream face, with an additional $2/3$ reduction at the drilled drains (if used). The impact of this uplift reduction on stresses and the required strength can be very significant (Schrader and Rashed, 2002).

Roller-compacted concrete dams have been constructed with axes that are straight or curved, with two intersecting straight axes, and with a combination of a curved axis with straight tangent axes. Both vertical and sloped upstream faces have been used. The downstream face can be vertical or at any slope. Within a given section, the downstream slope can be infinitely adjusted, curved, or parabolically shaped. Extensions of the toe, deeper excavations, and keys have been used to provide stability over poor rock and bad foundation conditions. RCC dams can be any height, ranging, for example, from 6 ft (Ferris) to 25 ft (Kerrville), 47 ft (Winchester), 125 ft (Copperfield), 160 ft (Monksville), 170 ft (Aulouz), 210 ft (Concepcion), 270 ft (Urugua-I), 300 ft (Trigomil, Rompepicos, and many others), 620 ft (Miel I), 660 ft (Longtan), and approximately 900 ft (Diamer Basah). The primary areas requiring special attention in RCC dams are overdesign strength requirements for variability, design section options, upstream and downstream facings (facings apply also to rooms in RCC masses, facings of RCC walls, and other non-dam applications), and thermal stresses.

20.5.2 Overdesign Strength Requirements

Overdesign average strength requirements for variability are required by most codes for general conventional concrete construction. Sometimes the overdesign is achieved through an arbitrary extra factor of safety applied to the required design strength, but, more appropriately, specific statistical procedures such as those outlined by the American Society for Testing and Materials (ASTM) or the American Concrete Institute (ACI) are used. European practice accomplishes the same thing as ASTM and ACI by using a specified characteristic strength, which is the strength below which not more than a certain percentage of individual strength tests is allowed. Until recently, it was not common to apply these statistical procedures to dam construction. In the earlier days of concrete dam design and construction, various arbitrary methods were employed to provide a reasonable overdesign in dams, or only an average strength was used and nothing was done for overdesign that accounted for variability.

Overdesign is an increase in the average strength requirement to account for the fact that not all cylinders will test at exactly the design strength level. Some will be higher and some will probably be lower. The overdesign factor is a method of limiting the probable number of low strengths to acceptable levels. Special care is necessary when applying overdesign factors in mass concrete, including RCC, because any extra cement used to increase the average strength may result in an unacceptable increase

in thermal stresses as well as cooling costs. Also, in high-production RCC where the results of final long-term cylinder tests are not available until the structure is essentially complete, testing of variability in the fresh mixture being placed has developed as a practical method of immediate control rather than using cylinder strengths, which are more for a matter of historical record. The overdesign requirement and its early application to RCC dams are discussed in the early literature (Schrader, 1987). Current recommendations and practice are discussed in detail in recent literature (Schrader, 2007).

Current practice for structural concrete (e.g., in an important beam or column) is to require an average strength sufficiently high so more than a limited number of test samples (typically 1, 5, or 9%) fall below the design strength. ACI Report 214R (ACI Committee 214, 2002) allows different percentages to be used based on the criticality of the incidence of an area of low strength in the structure. Using ACI 214R guidance, traditional accepted practice for mass concrete dams, and a sensible approach, it is reasonable to require the average strength of mass concrete to be sufficiently above the design strength to statistically ensure that not more than 20% of the test samples will fall below the design value. This makes good sense because an area of low strength that represents, for example, 20% of a lift or placement will not normally have a critical impact. Mass concrete dams are typically designed to have a factor of safety of about 3 built into the stress analysis, so being 20% below the design strength is still about 2.5 times more than the applied stress for the normal load condition. More importantly, stresses in an area of low strength (or a void with no strength) will redistribute around that area to adjacent areas of higher strength.

The importance of taking a reasonable approach to overdesign for variability in mass concrete, including RCC, is often overlooked. Requiring a higher average strength requires using additional cementitious materials. Doing so increases costs, but, more importantly, it also increases heat, thermal stress, stiffness of the mix (modulus), and therefore thermal cracking stresses. Arbitrarily increasing the average strength may seem like it would result in a better dam, but the reality is that it can result in a more expensive dam that cracks, rather than a less expensive dam with adequate strength that does not crack.

20.5.3 Design Section Options

Design sections and facing options for large and small RCC dams are summarized in the literature (Schrader, 1993). The variety of basic cross-section options that are generally available for RCC dams are shown in Figure 20.42 and Figure 20.43. The same options could be applied to conventional concrete, but the cost and construction methods used in conventional construction make most of them impractical. Figure 20.42 is a typical section for a low dam or a dam on a gravel foundation. The extra effort and costs required for a formed vertical upstream face usually are not worth the effort in a low RCC dam. It is easier, less expensive, and faster to simply overbuild the dam at the upstream face without forms. In addition to simpler construction, the extra mass provides additional safety within the RCC and may allow less stringent specifications or inspection. It may also justify using mix designs based on the designers' judgment without prior testing and local pit-run aggregate.

Compressive and shear stresses in a low RCC dam are so small they are almost meaningless. If the structure is subjected to overtopping, a reasonable level of bond between the top lift joints is necessary. This can be accomplished by applying a bedding mix between the top several RCC layers. Cement contents for very small dams are usually dictated by exposure conditions, mix workability, gradation of the available

FIGURE 20.42 Small dam section options.

FIGURE 20.43 Large dam section options.

aggregate, quality of the mixing equipment, and degree of inspection. Small dams that may require a cement content on the order of only 50 lb/yd³ for structural loads should have higher cement contents, usually on the order of 150 to 300 lb/yd³, to account for these factors. For small dams with volumes on the order of several thousand cubic yards, the cost for the extra cement is insignificant. Extra cement is helpful when placing in cold weather due to the heat it generates. Thermal cracking in a structure of this size and shape normally is not a structural problem. When necessary, watertightness can be provided by using fast construction, a high-cementitious-content wet-mix consistency, an upstream membrane, or a bedding mix between layers at the upstream face. Some structures do not require watertightness.

A downstream slope of 0.9:1.0 (0.9 horizontal distance to 1.0 vertical distance) or flatter is suggested for low dams because it is easy to build with any RCC mix. The extra RCC material involved is negligible. The top width should be selected as the minimum that allows reasonable construction with equipment typical of small projects. The contractor should be allowed to overbuild for his convenience at no additional cost to the owner. A suggested absolute minimum width is 12 ft. Two concerns are required access (if any) after construction and minimum widths for compliance with applicable safety regulations. Fill material can be used at the upstream (or downstream) face of the dam to steepen the slope, narrow the top width of RCC, and save volume if this becomes economical or if the topography requires it. When placed at the downstream face, the fill hides minor seepage and protects the RCC from exposure. If impervious fill is used at the upstream face, it can provide improved watertightness. When fill is used to steepen the RCC slopes of a dam on a non-rock foundation, consideration should be given to the increase in bearing pressure and sliding that will result at the base of the dam.

Small RCC dams on pervious foundations may require a cutoff or grouting for foundation stability or seepage control, but usually it is faster, less expensive, and easier to spread the foundation of the dam out through wider lower lifts and to use apron slabs of RCC. Settlement studies and a slab/beam analysis of the lower lifts establish how far the extension can go without the slab or apron breaking off. The flow path will also influence the apron width. A simple cutoff wall placed into an excavation without forms is recommended. The downstream cutoff and apron normally should have drain holes.

Figure 20.43 illustrates many of the options or variations for a typical gravity dam section that are practical with RCC for larger projects. Variations and options are labeled 1 through 17 in the figure. The basic gravity section with a vertical upstream face, constant downstream slope, and a vertical downstream

face at the top of the dam has been used for many RCC dams; however, the low cost of RCC often makes it reasonable to flatten the downstream slope and add more mass than conventional concrete allows. This reduces foundation stress, RCC strength requirements, and lift-joint concerns. Reductions in cement content with related reductions in unit cost and in thermal stresses result. The possibility of using higher cementitious contents with higher strengths should also be investigated if the thermal stresses can be tolerated and the volume reduction offsets the increase in costs due to higher unit costs of the RCC. Influencing factors are the length of diversion, the cost and availability of cement and pozzolan, the quality and production costs of the aggregates, and foundation quality.

A parapet wall (2) can reduce costs by reducing the quantity of RCC. The wall can also act as a personnel barrier and curb. Added height, or *freeboard*, for overtopping waves is not necessary with RCC. Also, by curving the top of the parapet outward, it can return waves by directing them back to the reservoir. The wall can be a continuation of upstream precast panels if that option is used to form the upstream face of the dam. A breakaway parapet (fuse plug) designed to fail during overtopping can be designed. One reason to do this is so water flows over one side of the dam while any downstream powerhouse or access road on the other side remains protected.

The width of the dam (3) should be established after considering a number of factors, such as the cost of additional RCC and downstream vertical facing; the required (not just “nice to have”) width for access during operation and construction; inertia (seismic loading) of the laterally unsupported top section of the dam; the effect of the mass on sliding stability due to the added confining load; the effect of the mass on the location of the resultant force for the entire section; the distribution of foundation stresses; and the possibility of causing tensile stress across downstream lift joints for a high dam in the reservoir empty condition.

Adding mass and width to the dam at the base by using a sloped upstream face (4) may efficiently improve stability. An extra benefit is the downward vertical component of the reservoir load on the horizontal projection of the dam face. A condition to check is whether this causes tensile forces to develop or to become unacceptable at the upstream face in both the foundation and lower RCC lifts. Slopes up to about 0.10 (H):1.00 (V) can be practically built in most RCC dams without noticeable effect on the cost, schedule, or construction practicality.

Tension at the upstream face of both RCC and conventional concrete gravity sections is a controversial issue. Each project should be evaluated for its own set of conditions. What may be acceptable for one location and type of mix may be unacceptable for a different location or mix. The majority of designers and regulating codes in most countries consider that gravity sections should have little or no tension at the upstream face in the normal reservoir or normal operating condition. Minor tension is occasionally allowed for severe flood conditions; however, it is reasonable to provide high-cementitious-content mixes or bedding mixes across lift joints near the upstream face to accommodate the need for small but sustained tensile stresses on the order of a few percent of the compressive strength for the normal operating condition, if this is necessary to achieve an economical design in high dams. Allowing for softening of the foundation with a lower tensile mass modulus at the heel of the dam will also reduce this tensile stress. It is reasonable to allow minor tensile stress for flood conditions at isolated areas of good inspection or special construction treatment when necessary. For seismic conditions, tensile stress is usually unavoidable and allowed up to 150% of the expected static tensile strength to account for the increased tensile strength under very fast loading. This increase is referred as the *dynamic increase factor* (DIF). With this allowed stress, a factor of safety just greater than 1.0 is typically accepted under earthquake conditions, with higher factors of safety for flood and normal load conditions. Table 20.10 provides a simplified summary of the required safety factors and allowed stresses for various load conditions under different code or agency requirements.

Galleries (5) in RCC dams should be minimized. There has been a tendency to extend galleries beyond where they are actually needed. This causes higher costs, slower production, and lower overall RCC quality. In large open areas, such as at the base of a high dam section, galleries typically slow production by about 15% for the uncemented fill method of construction. Conventional forming slows production even more. In the upper portions of the dam, where there is less room, the decrease in production at the area of a gallery can be 50% or more, and the quality of placement may decline significantly. Where

a gallery is actually needed high in a dam for uplift, an open graded rock drain of coarse aggregate should be considered (6). If placed about four lifts high, it is possible to excavate the drain for access if necessary in the future. The vertical distance between galleries is usually determined by the accuracy with which equipment can drill from the floor of the top gallery to intersect the roof of the gallery below. This typically is about 100 feet for a gallery 6 feet wide, using rotary percussion drilling equipment operating from the floor of the upper gallery. In addition to interfering with construction, a gallery high up in a dam can also be a point of weakness in a seismic event (7). Designers of low- and medium-height dams

should consider simply overbuilding the dam enough so galleries and drains are not even necessary. The unit cost of the RCC decreases, and construction, operation, and maintenance are simplified. An example of this is Winchester Dam. Using a bedding mix between lifts or a high-cementitious-content RCC is suggested upstream of galleries and between the first three layers in the area above and below the gallery floor and ceiling. This provides watertightness, bond against uplift below the floor, and added sliding resistance against reservoir pressure at the upstream gallery wall.

A **grout curtain** (5B) can be installed prior to the RCC or can be installed afterward from a gallery. The gallery should be large enough to accommodate suitable production equipment, especially at interior corners and intersections. Internal drains (5C) can be easily drilled with track-mounted rotary percussion equipment. Nominal 3-in. holes at spacings of 10 to 15 ft are adequate. These holes can be drilled at high production rates with an accuracy on the order of ± 3 ft in about 120 ft. A very efficient way to drill these holes is immediately after placing the RCC lift that is the gallery floor. When a long gallery with holes beginning at the same elevation is called for, it is effective to stop RCC for a day while several track drills drive onto the lift and drill the holes. The area is then cleaned, treated as a cold joint, and the RCC placing resumes. High dams, dams with wide bases, dams with high heat (due to high cement contents, use of high-heat cement, or hot placing conditions), and dams with high elastic modulus values may require longitudinal joints (5D) that can be grouted from a gallery or from outside of the dam. A practical way to make this joint is to simply place open-graded coarse aggregate at the joint location as each RCC lift is spread. The RCC is then compacted with the aggregate (5D). Grout tubes are installed in the aggregate as it is placed. Before raising the reservoir but after sufficient cooling of the mass, the joint is pressure grouted from the bottom up with expansive grout. A continuous monolithic concrete mass results instead of two masses connected by a thin grout line.

Using a **fillet** (7) in the upper part of the dam at the downstream face provides additional weight that improves sliding stability and offsets some uplift pressures. On a high dam, it moves the resultant force of the entire dam section slightly upstream, whereas on a low dam it shifts the force downstream. The distribution of stress under the dam, the amount or existence of tensile stress, and the maximum compressive stress are slightly affected. The fillet also reduces the height of the section at the top of the dam. A downstream toe extension (8) can provide additional stability for a high dam where sliding stresses increase significantly with a minor addition in height. It adds both weight and total cohesion, but only in the bottom portion of the dam, which is usually where it is needed. The fillet (7) increases the mass across the full length of the dam, including the upper portions of the foundation where it usually is not needed. The fillet also adds to foundation bearing and RCC compressive stresses, whereas the toe extension reduces the bearing and maximum RCC stresses. The extended toe requires extra excavation and foundation preparation but only in the deepest section of the dam and not for much of its length. It is possible that an extended toe in a high dam will result in tension across downstream lift-joint areas at the maximum height for an empty reservoir condition. This can be overcome by an early partial reservoir filling.

A **key** (9) is an effective way of providing additional sliding stability when it is needed in the foundation but not in the RCC. Although adding the key near the upstream face may seem like a good idea because of its potential to act as a cutoff, the downstream location will typically be better. If analyzed for local stresses, an upstream key of a high dam may have tensile forces that could negate sliding friction resistance because there will be little or no vertical stress at the key and a full reservoir. A downstream location has the benefit of maximum vertical confining stresses and the resulting friction. To minimize the width of the key (upstream–downstream) and to ensure that the required load is transferred to the foundation without slippage across a weak RCC lift surface, bedding mix should be placed between RCC layers in the key or a high-paste-content mix should be considered. The key provides added foundation stability by extending the foundation failure plane (12) and by the related horizontal component of the downstream foundation-bearing capacity (13). A relatively simple consolidation grouting program in the area downstream of the key may significantly improve stability. A key is usually required only in the deeper portion of a high dam (if it is on medium- to poor-quality rock), at isolated locations where the foundation condition is bad, or for a medium-height dam on an unsuitable foundation.

When the bearing and sliding strengths of a foundation are poor, a conventional concrete dam usually is not economical, but RCC can be a viable option. Using a low-strength and low-cost RCC with a parabolically curved downstream face (10) is one approach. At the PC-1 project, a preliminary design with this concept was prepared for a tailings dam on a clay and weathered-rock foundation. The dam was composed of large monoliths that could undergo significant independent movements caused by time-dependent consolidation of the foundations. Each monolith sat on its own excavated foundation, with steps in the foundation matching the location of monolith joints. The abutments were tied in with embankments that would undergo deformation as required. The foundation for this project was so poor that a massive key was required to provide sliding resistance and to lower the bearing pressure. Because **foundation restraint** is minimal for this type of foundation and cement contents are low due to the low strength requirements, thermal stresses are minimized; however, the thickness of the key (distance from the downstream surface to the foundation under the key) should be analyzed as a cantilevered beam to ensure that it will not break from the rest of the dam. If bearing pressures under the key can accept the added weight (15), then a fill (14) can be placed over a portion of the toe to offset some of the cantilever forces. The fill also provides extra sliding stability if it is extended downstream beyond the RCC key. Regardless of which option is used to widen a dam base, a reduction in bearing pressure and maximum stress occurs in the RCC. Reduced strength requirements lead to less cement being used, lower costs, and less thermal stress. Stresses at the lower levels are closer to stresses higher up in the dam, so fewer zones requiring different quality RCC at different heights are necessary.

Although structural requirements for strength reduce to zero at the top of a dam, some minimum strength is needed for erosion and weathering protection, impermeability, and making the mix cohesive enough to be placed and compacted. The minimum RCC strength should be based on factors such as exposure conditions, function of the dam, risk level, and economics. What is appropriate for one project, owner, and location may not be appropriate for another project, owner, and location. There is some disagreement, but minimum strengths at 1-year values of about 1000 psi have been considered acceptable for the mass. Early RCC dams used higher strength mixes for the upstream and downstream regions and lower strength RCC at the interior. This proved to be a more serious construction and inspection problem than anticipated. The practice is now generally avoided. In addition, other factors have influenced this trend, including the good field performance of low-strength RCC exposed at the downstream face under severe weather. If needed, RCC can be protected at the upstream face by constant immersion in the reservoir, by an unbonded impervious membrane (with or without protective precast facing panels), and by conventional concrete placed using one of many possible techniques. The downstream surface can also be protected.

It is usually best to use one mix throughout an entire section for small- and medium-sized dams up to about 120 ft in height. Due to thermal and economic considerations, higher dams are usually separated into horizontal zones, with higher strength mixes being used in the lower part of the structure. Generally, these zones are on the order of 30 to 60 ft thick, with increases in strength of about 100 to 500 psi per zone. Initial planning for the 340-ft-high Binongan Dam used four zones. The design for the 620-ft-high Miel I dam used eight zones. In addition to the higher compressive strengths required for higher **principal stresses** in the lower portion of high dams, stronger mixes in the lower zones also provide additional lift-joint tensile strength, added cohesion, and usually a slight increase in friction.

When a mix in a lower zone has adequate strength for compression but not for sliding stability, several options are available. Increasing the mass or weight of the dam and widening the base have been discussed. Increasing the paste content of the mixes is another option, if it is economical and does not cause thermal cracking due to added heat from hydration or a higher elastic modulus. Another option uses bedding between RCC layers. As discussed in Section 20.4, this dramatically increases cohesion and moderately increases friction. This technique is especially useful when cold joints occur in low-paste mixes. Contract drawings can simply show where bedding mix is necessary for both cold joint conditions and, in some cases, with weak RCC mixes for fresh joints (15A).

20.5.4 Upstream and Vertical Face Options

Design options for the upstream face are detailed in the various sections of Figure 20.44 labeled 16A through 16M. If the upstream face is sloped (16A), the unformed face may be left exposed when it is aesthetically acceptable and when lift-joint seepage is either tolerable or controlled with bedding or higher cementitious content RCC. If total watertightness is required and special mixes with rigorous lift-joint inspection are not utilized, a flexible geomembrane can be placed over the sloping face (16B) (Schrader, 1999b). Where the membrane is exposed, it can be protected from removal by vandals by hanging a chain link fencing over it or by other methods. Below grade, it has been protected from damage by a layer of sand.

Reinforced conventional concrete placed after the RCC (16C) uses the same design concept as an upstream face on a rockfill dam. If the wall is thick enough, it is feasible to construct it ahead of the RCC with traditional slipformed or jump-formed construction. This allows the RCC to be placed rapidly as a trailing activity, with the RCC placed directly against the wall. There is no forming to delay the RCC operation. The wall is the form. It also acts as a thermal shock protection for the RCC. The wall will provide an attractive and watertight facing when properly designed and constructed. This requires slabs with water stops in the vertical and horizontal joints. A *plinth*, or watertight tie-in to the foundation and abutments, is required. Two-way reinforcing distributes shrinkage cracks throughout the slab so cracks are small and closely spaced. By limiting the crack width to about 0.006 inches, the cracks will be essentially watertight and typically undergo autogenous healing or calcification with time, even under hydraulic head. A drain system is necessary between the slabs and the RCC. Anchors are required to hold the slabs to the dam. These should be designed for the force due to horizontal acceleration in an earthquake. It is possible but difficult to position the anchors in the RCC when it is placed; drilling and grouting them afterward is the alternative. This concrete-facing method is often considered but is seldom designed or used. An extension of the concrete-faced option (16D) includes a second facing of porous concrete that acts as a total drain between the RCC and the upstream face. This also isolates the RCC from shrinkage and potential cracking or joint requirements in the facing, and it acts as thermal insulation to reduce gradients near the face. It was included as an option for the RCC design option at Kapachira Dam.

Roller-compacted concrete can be placed directly against conventional forms, but without a conventional concrete bedding or facing the degree of compaction and appearance will be compromised. Threaded anchors to the forms can be compacted into the RCC. After the RCC has been placed high enough so the next form panel can be positioned and anchored, the lower form can be slid out along the anchor and away from the RCC mass (16E). The void between the RCC and form can then be filled with conventional concrete that bonds to the young RCC and is mechanically held by the anchor. Instrumentation has shown that, by controlling the rate of placement and set time of the concrete with this type of procedure, form pressures can be developed that will stress the anchors and prestress the face in place.

Precast panels (16F) make an attractive, economical, and crack-free facing, but the panel joints are not watertight. Anchors are minimal, usually about 75 ft² of panel per in.² of steel anchor area. Watertightness can be provided with a flexible PVC membrane (about 0.08 in. thick with welded field seams) attached to the back of the panel. A nut and washer tightened against the membrane with epoxy provides a watertight seal where the anchor penetrates the membrane. This procedure has been very successful in construction, operation, and tests to a head of 600 ft. A small amount of bedding is recommended between the membrane and RCC. Drains should be provided behind the membrane to collect seepage if it occurs and to provide additional stability by creating extra uplift reductions.

Roller-compacted concrete can also be placed against a conventional form that is later removed. A small amount of bedding against the form has helped to seat the form and provide a better surface. When done properly, this will result in a conventional concrete appearance, with RCC immediately behind the face; however, it requires a mix and technique that not everyone has been able to accomplish with total success. At times, difficulties have been encountered when the bedding has not squeezed up the form face, resulting in a boney look to the RCC at the exposed face. Another way to accomplish the appearance of a conventional concrete face is to use grout-enriched RCC (GERCC), with or without an air-entraining admixture as discussed in Section 20.3.6.

FIGURE 20.44 Upstream face options.

Watertightness can be established with an exposed polyvinylchloride (PVC) membrane placed directly against the dam face (16G) (see Section 20.4.16). The membrane requires an anchored but unbonded procedure specifically developed for concrete dam facings. A variety of synthetic membranes was used in earlier projects, either with drains or without drains. These systems worked satisfactorily, but were not entirely successful. A specially formulated PVC membrane produced and installed by the Carpi company was then adapted to RCC, using technology and proven performance from its application to provide watertightness at older conventional concrete dams with seepage and permeability problems. This membrane has routinely provided total watertightness at the upstream face. The installations include a face drain system. The Carpi exposed-membrane system has been installed with 100% success for more than 20 years on a number of RCC dams and for much longer in the rehabilitation of leaking old conventional concrete (Scuero and Vaschetti, 2003). Drains between the membrane and RCC improve stability through additional uplift reduction, as discussed in Section 20.4.16. Simply extending the bedding mix downstream along the lift joint (16H) for a distance equal to at least 8% of the hydraulic height will provide watertightness if it is done 100% correctly 100% of the time. In practice, this is not possible. Normal construction with good inspection results in about a 95% reduction in seepage; this may be technically but not aesthetically adequate.

A number of RCC dams, and the facings of rooms and walls on other RCC mass applications, have been built that using the procedure labeled 16I in Figure 20.44. The procedure results in an attractive conventional concrete face that is completed with the RCC. Usually, the facing has no anchors to the RCC and no reinforcing bars. If a low-water/low-cement/low-shrinkage conventional concrete mix containing a high-range water reducer is carefully used and controlled, a virtually crack-free facing can result—even without vertical joints. The mix should not be thicker (horizontal dimension) than about 1 ft, or thermal and shrinkage cracks will probably result. Excellent curing must be provided. Without these precautions, tight cracks at spacings of about 4 to 10 ft can be expected. Normal construction with a reasonable mix will be crack free if joints are provided in the facing about 25 ft apart. The problem with joints in a facing is that it is very difficult to install water stops. Various projects that have attempted this have had less than watertight joints. The facing does not make the horizontal lifts watertight. If placing proceeds very quickly (about four to six lifts per day), the fact that the successive layers are placed before the previous layer has fully set will improve watertightness of these joints.

A modified procedure (16J) uses a temporary blockout near the upstream face at every other RCC lift. The blockout is removed prior to placing conventional facing and the next RCC lift. Each face placement covers two RCC lifts. Added watertightness can be achieved by using a simple *swelling-strip* water stop that is impregnated with chemical grout and laid along the facing mix lift surface. If seepage penetrates the lift joint, moisture causes the strip to swell, thus creating watertight pressure against the adjacent lift surfaces.

Interlocking upstream-facing elements (16K) have been precast and slipformed. As precast pieces, the upstream area covered by each piece is only about 10 ft² of exposed surface area, so production and placing becomes labor intensive and slow. The small area is a result of the weight of the thick and overlapping shape. The joints are not watertight, and there is some concern regarding the stability of the facing if it is not anchored to the RCC. Horizontally slipformed facing can slow production of RCC on dams with a short axis, but the procedure and equipment are better suited to long dams with a large volume of RCC per lift. Careful control of the mix and its delivery is critical, and the facing will develop small shrinkage cracks. RCC can be placed against the facing the same day it is slipped. Consideration should be given to the bond between the unanchored facing and RCC. This may require a high-paste RCC mix against the slipformed facing. Sandblasting may be necessary to achieve a bond if the facing is old before the RCC is placed against it. The possibility and consequences of saturation and freezing at the bond line should be evaluated.

Dams in steep canyons, and some large projects, can benefit from an upstream wall (16L) placed across the valley. Such a wall acts as an upstream form for the RCC or as a starting wall for concrete facing and membrane systems. It protects the foundation by containing water and debris, and it allows fill to be placed against the upstream side of the wall, thereby creating a practical work area that extends to the

FIGURE 20.45 Downstream face options.

face of the dam. Projects such as Copperfield have saved time and money by placing backfill lift by lift with the RCC to create a vertical upstream face without forms (16M). This is fast and effective and provides a long level surface upon which subsequent forms can be set when the maximum practical height of backfill is reached. Regardless of what procedure is used for watertightness, a tight contact is essential at the interface between the upstream face and foundation. Details regarding this contact and how it varies from one upstream facing or water barrier method to another are beyond the scope of this chapter.

20.5.5 Downstream and Sloping Face Options

The downstream face of the dam, or any other sloping face, can be designed using any one of the many options shown in Figure 20.45 and labeled 18A through 18G, as well as with GERCC as discussed in Section 20.3.6. A common, economical, and practical method uses steps with a small amount of bedding placed against reusable-form panels (18A). The panels are one to three lifts high, moveable without equipment, and held by simple methods such as pins hammered into the RCC after compaction. By changing the width of the steps, any average or changing downstream slope can be achieved. If a conventional concrete appearance or protection from weather is desired, conventional concrete can be used for the facing (18B). Larger steps (e.g., if needed in a spillway) can be built with variations of this method (18C and 18D). Reinforcing steel and anchors are not required with a monolithic construction procedure, but with low-cementitious-content mixes it is essential that the conventional concrete be placed first with a mix that will have lost its slump but not reached initial set by the time the RCC is spread against it and compacted down into it. If the RCC is placed first, the result will look good at the surface, but there will be no reliable contact or interface between the two mixes. Anchorage is then necessary and the RCC should first be compacted at the edge (18D). Smooth spillways and downstream sloped surfaces have been designed and constructed using no treatment except for hand trimming (18E), unreinforced and unanchored conventional concrete facings with about a 1-ft minimum width (18F), and slipformed concrete with anchors and two-way reinforcement placed after completion of the RCC and after substantial chipping or preparation of the RCC (18G).

20.5.6 Thermal Considerations

Concrete produces heat when it hydrates and hardens. This is of little consequence to small placements, but it is of major concern to massive placements. If heat from hydration is trapped within the mass, the internal portion of the mass will harden and stiffen at an elevated temperature. Later, as this heat slowly escapes, the mass will try to contract as it cools. If the mass is restrained (e.g., by being bonded to a rock foundation), it is prevented from contracting. The attempted thermal strain is therefore converted into tensile stress. If the thermal stress is greater than the tensile strength, cracking will occur. Because massive structures typically have little, if any, reinforcement, the stability of the structure usually depends on an uncracked section with internal tensile stresses less than the cracking strength of the concrete.

Roller-compacted concrete provides several opportunities to reduce internally developed thermal stress. Its lower cement content reduces the total hydration heat in almost a direct proportion to the cement reduction. If the mix has a very low cementitious content, the stiffness or brittleness (modulus) of the concrete can be low, and substantial stress relaxation due to creep can occur. Although it can be done, it is not very practical or economical to provide forced post-cooling; some of the traditional methods of precooling, as with ice and chilled water, are also not very economical or effective. Producing aggregates in cold winter months and storing them in large stockpiles until they are used in warmer months has resulted in reduced placing temperatures. This has the same overall impact as using a submerged chilled wet belt or cold air to precool the aggregate, but it is essentially free, and it applies to both fine and coarse aggregate, whereas submerged wet belts can only be used on the coarse aggregate. In addition to controls on aggregate production, the rate of placing, hours of placing (night vs. day), and the schedule for starting and finishing placing are critical factors for thermal stress analysis. The designer must pay attention to these details and consider them in the thermal evaluation.

Thermal evaluations for RCC mass placements require much more attention to detail than is necessary with traditional mass concrete. There are several reasons for this, but the most important is the large exposed surface area for each thin layer of RCC mass that is placed in each lift. Conventional concrete uses a much smaller exposed surface area with a thick layer of concrete mass for each lift. The heat transfer, either by heat lost to the atmosphere or by heat gained from exposure to the sun, is consequently a much more critical aspect of RCC thermal studies. The time of placement of each layer or lift of RCC can also be a very significant factor, whereas the time of day for placement of conventional concrete is not as important. A low-cement-content RCC mixture may have an adiabatic temperature rise that is less than the heat absorbed from the sun before the layer is covered with the next layer of RCC. In this case, placing at a faster rate can result in lower temperatures—exactly opposite of what would occur with normal placing of conventional mass concrete. Details of thermal analyses are beyond the scope of this chapter. Various references contain examples and suggested methods for analysis (Ditchy and Schrader, 1988; Hirose et al., 1988; Tatro and Schrader, 1985, 1992; USACE, 1997).

When properly accomplished with detailed input of the time-dependent construction schedule, finite-element method (FEM) temperature analysis can accurately predict the temperatures of any RCC mix at any location in a structure at any time. This usually requires consideration of the time of day for placement of each layer of RCC, the variable temperature throughout the day, the movement of air across the lift surface, and an accurate determination of the adiabatic temperature rise of each mix. It also requires knowing the physical thermal properties of the materials, considering the type of cure and evaporative cooling, and considering probable interruptions to the placing schedule.

Thermal FEM studies can be simplified by using one-dimensional, heat-flow studies for the more massive sections of a structure, with two-dimensional analysis being reserved for areas of smaller dimensions on the order of about 20 ft wide. The results of the individual studies can then be combined to create a three-dimensional time-dependent result. Using multiple one-dimensional heat-flow analysis where possible can actually be better using than two- and three-dimensional studies because it allows better detailing of the FEM mesh, with nodes at the interface of every lift. This typically is every 12 in. throughout a structure that extends hundreds of feet in each direction. The exact time of placement of each lift can then be taken into account. Large two- and three-dimensional models that are suited to traditional concrete placements with a large mass being placed only every few days typically have much larger node spacings and are unable to account for the detailed placing of RCC in 1 ft layers every 3 to 16 hr.

Figure 20.46 provides a conceptual approach to using one- and two-dimensional models to properly study a large RCC mass. Figure 20.47 shows the results of a study performed with this methodology and gives an idea of the temperature distributions within a structure that used RCC ranging from very lean cement contents in the center of the structure to higher cement contents in the outer 9 ft of the dam. The thermal contours are based on actual field measurements. The temperatures in square boxes indicate the predicted temperature for that mix, location, and time. Predictions were within a degree or two of the actual conditions.

FIGURE 20.46 Sample finite-element method (FEM) mesh for thermal studies.

20.6 Construction

20.6.1 General

Construction is discussed in general in ACI Committee 207 (1989), Oury and Schrader (1992), and Schrader (1991, 1992, 1995a,c,d, 1999b, 2002). There are many examples in the literature of RCC construction methods used at specific projects and their interrelationship with RCC design issues at, for example, the Burton Gorge, Rompepicos, and Burnett dams (Schrader, 1999b; Schrader and Bali, 2003, Lopez et al., 2005). Because of the interrelationship between mix designs, structural design, material properties, and construction, many aspects of construction have been discussed, at least in part, in the previous sections of this chapter. It is important for the contractor to understand that construction equipment and methods have a direct effect on design and that some procedures, production rates, and equipment may not provide the quality or characteristics required for a particular design. What is acceptable for one design and set of conditions may not be acceptable for a different design or set of conditions. Some examples of the interrelationship of design and what may seem like simple construction decisions follow with regard to positioning of supports in the dam for RCC conveyors and how RCC is started at the foundation.

Many RCC dams are constructed using an all-conveyor system, with the conveyor being supported on posts within the dam. The posts are pulled up and raised as the dam is built. Before sufficient RCC has been placed to support the posts, they require a substantial footing. Without proper design considerations, these footings represent fixed rigid blocks protruding into the dam with vertical faces that could initiate cracking both from the perspectives of restraint to thermal contraction and the tendency for the formed vertical face to propagate into the RCC as a crack.

One way to deal with the restraint from objects such as these is to place them at the center of monoliths, or so one face of the footing is flush with a monolith joint. Because thermal contraction is toward the center of the monolith, movement will be from the free face of the monolith joint toward the center, which is already the position of maximum restraint. Footings located here should be bonded to the adjacent RCC. Ideally, footings near the middle of a monolith should be circular, without corners. If the

FIGURE 20.47 Predicted vs. actual internal temperatures.

footings have corners, they should be rounded or chamfered. In addition, consideration should be given to reinforcing the RCC in front of corners by dropping bars into these lifts as they are placed. If the footings are located at monolith joints, square footings can be used. In this case, the faces of the footings should be debonded from the RCC (e.g., with curing compound) so the monolith can contract away from the fixed rigid restraint of the footing.

A much preferred approach to footings above the foundation is to avoid them by setting the posts into the foundation. This can be done by drilling large-diameter holes into which the posts are placed. Another procedure that has been used is excavating into the foundation with careful blasting or hydraulic hammer excavation and then filling the hole with dental concrete. The top of the dental concrete is finished flush with the top of the surrounding foundation. The dental concrete block becomes part of the foundation. The post is embedded within the dental concrete. Because this approach eliminates the problem of a rigid block protruding into the foundation, it allows placing the posts at almost any location, with a general guide that they should not be closer than about 2 m from a monolith joint. The posts jack-up out of the foundation as RCC is placed.

Similar to the issue with massive footings above the foundation, concrete (including RCC) ramps should also be avoided within the RCC, unless their impact on design, including thermal restraint and potential for propagation of a ramp face as a crack into the RCC, is adequately addressed. If ramps are to be constructed and left in place, they should use RCC of similar quality to the RCC in the dam, and the position of the ramp should usually be toward the middle of a monolith. Because of restraint, ramps on the foundation require more attention than ramps that are within the RCC, above the foundation.

Some RCC projects have used leveling concrete to cover the foundation and provide a smooth base from which to start RCC, whereas other projects start with RCC directly on the foundation. There are arguments for each approach. Considerations for and against the use of leveling follow. Leveling concrete simplifies the start of RCC placing and its initial production rate, but it requires considerable time to construct, and it uses concrete that is more expensive than RCC, with different properties than the RCC. If the RCC or foundation has a high tensile mass modulus similar to conventional concrete, the leveling concrete will simply be another material with properties similar to what is above or below it, so this is of less concern. If conventional concrete is used for leveling on a foundation with substantial undulations and slopes, it will be very thick in most locations. This will require thermal controls that usually involve forced cooling of the leveling mix. If the project already has ice capability for other purposes, the problem is not difficult to overcome, but if no cooling capability would otherwise be necessary then this becomes a major expense. In addition to thermal cracking, consideration should be given to drying shrinkage. This requires the leveling mix to be continually cured until it is covered with RCC.

Formed vertical and clearly defined joints should be avoided in leveling concrete unless they coincide with contraction joints in the RCC. This applies to both the transverse and longitudinal directions. A formed joint represents the start of a crack off the foundation and a stress riser (restraint) where thermal stresses are usually maximum. Some projects that have used leveling concrete and could not avoid extra joints due to concrete plant and placing capacity issues have later injected the joints with epoxy after they opened and before placing the RCC. Leveling concrete typically has long-term stiffness (modulus) values on the order of 20 to 35 GPa (3 to 5 million psi) with low creep. If this concrete is placed on a foundation with lower tensile mass modulus, it creates added restraint and therefore higher thermal stresses.

Any type of RCC mix can be placed directly onto foundation rock without leveling concrete. This is accomplished by first spreading a thin layer of high-slump bedding mix (with or without coarse aggregate) onto the rock and then spreading the RCC over the bedding and compacting it while the bedding is still fresh. This has been one of the most common procedures for placing RCC on foundations, and it has been very successful. The RCC compacts into the bedding so the two materials become one concrete, while the grout and mortar portion of the bedding conforms to the rock and provides total glued contact to it. No distinctly different material lies between the foundation and the RCC, which avoids the separate leveling mix and its concerns.

If the foundation is relatively poor and it would deteriorate from exposure prior to placing the RCC, it is common to use shotcrete or a thin mud mat of high-slump concrete to seal and protect it. The shotcrete typically is on the order of 50 to 100 mm (2 to 4 in.) thick, and the mud mat is 100 to 150 mm (4 to 6 inches) thick. Clearly defined formed edges should be avoided. The material will be subject to some cracking, but the cracks will be random. By keeping the mud mat thin, cracks will likely mirror the joints in the foundation rock and not propagate up into the RCC. Where shotcrete is placed against abutments and there is a tendency for the foundation underneath to still deteriorate or where the abutment could not be cleaned to sound material before shotcreting, grout pipes have been used to ensure a seal between the shotcrete and foundation. Each grout pipe should be an individual line, usually PVC, that is routed through the dam to a convenient location such as the downstream face for later grouting. It is imperative to maintain identification of each pipe so they can be grouted in a planned pattern after the RCC has been placed to a substantial height above the location. The pipes should not be interconnected.

Rapid construction is important to quality, simplicity, and profit in RCC projects. It is more difficult to produce quality construction at low production capacity than at high production rates. In general, RCC mixtures that do not contain a retarder should be delivered within 10 minutes of when mixing started, spread within 10 minutes of when they are delivered, and compacted within 10 minutes of when

they are spread. Typical specifications require that the elapsed time from the start of mixing until the end of compaction should not exceed 40 minutes. The exposed edge of RCC lifts should also be compacted or advanced within about 40 minutes of when the material was mixed. These time limits are good guides, but consideration should be given to the particular characteristics of each mixture, the temperature, whether the mix is placed in a critical part of the structure, and the practicality of construction.

A common characteristic of profitable and technically successful RCC dams is good communication between the contractor and designer, with decisions being made promptly and with authority in the field. Interruptions and slowdowns result in reduced joint and RCC quality as well as increased costs. Interruptions to a continuous RCC construction operation are bad for both the engineer and the contractor. Direct communications and procedures for on-site problem resolution are essential, without excess personnel, management, or administration. This sounds basic and simple, but it is amazing how many projects have suffered from insufficient authority, responsibility, and responsiveness in the field—from both the contractor and engineers. When problems develop at the placing area, they must be resolved quickly. In RCC construction, there usually are no alternative monolith blocks where work can progress while the problem is studied. When contingency plans for added monolith joints are approved in advance, it may be possible to raise a portion of a structure or massive placement ahead of the rest of the structure, but this can result in placing difficulties and the design implications must be considered.

Profitable and efficient RCC construction is machine intensive, with minimal labor per cubic yard of placed RCC. Equipment should do the majority of the work, not labor, even for smaller projects. The rare exceptions are special projects designed to be labor intensive in developing countries with the intent of employing a large unskilled labor force at low wages. Fueling, form work, and assembly of embedded items should all be scheduled and planned so the majority of this work is accomplished off the lifts and during shift changes or scheduled downtime. All unnecessary vehicles and personnel (including visitors and inspector trucks) should be kept out of the placing areas and equipment paths. It is essential for all materials, access, embedded parts, foundation excavation and preparation, and similar work to be planned and readied well ahead of time.

20.6.2 Aggregate

The location, size, and withdrawal of aggregate from stockpiles must be coordinated with the RCC plant location and method of feed to minimize segregation and variability. At the very high production rates possible with RCC, several loaders or a conveyor system may be required to keep feed bins full. The length of haul and size of turnarounds must be considered so loading equipment can operate rapidly, efficiently, and safely. Aggregate stockpiles and the concrete plant location can be even more important than in the production of conventional concrete. Typically, very large stockpiles that could easily be half the material needed for a season of placement are provided prior to starting RCC placement. Some of the reasons for this are as follows:

- Technical design requirements may require producing aggregate during the winter so it can be stockpiled in the cold for later use. At Middle Fork and Monksville Dams, winter stockpiling resulted in aggregates that still had occasional frozen areas when the material was withdrawn during the summer, although ambient temperatures exceeded 80°F. At Burton Gorge Dam, instrumentation showed that producing RCC aggregate at night resulted in a 10°F lower aggregate stockpile temperature than producing similar aggregates during the day.
- It may be relatively easy to mobilize aggregate production to full operation while work for the rest of the project is just beginning. It is customary to pay for aggregate in a stockpile at the job site if it is tested and found to be acceptable. Payment should be based on an appropriate percentage of the in-place cost of RCC, including some profit.
- The rate of aggregate use during RCC placing may exceed the aggregate production capacity. With large stockpiles, material that occasionally is produced out of specifications may be spread throughout the acceptable material to produce a blend that is within specification. Larger aggregate stockpiles also have the benefit of more stable moisture contents which reduces fluctuation in RCC consistency.

FIGURE 20.48 A large “all-in” aggregate stockpile with no segregation at Burnett Dam.

Although many RCC dams have been constructed with numerous aggregate size groups and stockpiles, many others have been very successfully constructed with just two size groups. Usually this is $+3/4$ in. and $-3/4$ in. Some projects have used a single, all-in size group. Figure 20.48 shows an all-in, 2-in. MSA aggregate pile at Burnett River Dam. As cost and production benefits are demonstrated on more and more projects, with excellent control of moisture and variability, minimizing stockpiles is becoming more popular. Fewer size groups mean less area for storage and less equipment for loading and transportation. Fewer aggregate bins are required, and less complicated mix designs are possible. A major benefit that is often overlooked is what happens if an aggregate feed bin malfunctions. If a plant has four bins and each bin carries a separate material, production stops if one bin malfunctions. If the same four-bin plant is used to carry only two size groups, at least one of the size groups would be fed with more than one bin. When a bin malfunctions, production can proceed, though at a slower pace, with the operating bins while repairs are made to the bin that is down.

When low-cementitious-content RCC mixes are used, it is necessary to include nonplastic fines (passing $75\text{-}\mu\text{m}$ or No. 200 sieve) to compensate for the otherwise low paste content. When fines are included with a size group of $-3/4$ in., the material is similar to a road base. It has minimal tendency to segregate, especially if it is damp. Also, the moisture content in the pile tends to stay very uniform because the material is not free draining. This is not the case with traditional washed concrete aggregates. Very large and high stockpiles of $-3/4$ -in. RCC aggregate containing nonplastic fines have been built in layers. The aggregate is later removed without segregation by a front end loader. A potential disadvantage of handling an RCC aggregate with nonplastic fines is its tendency to compact in bins and bridge small gate openings unless special precautions are taken.

20.6.3 Mixing

A comprehensive discussion of RCC mixing and delivery philosophies and specific concerns about handling RCC is available in Oury and Schrader (1992). This reference also includes details and experiences, beyond the scope of this chapter, that are pertinent to a wide range of RCC mixing and delivery equipment types. The concrete plant location should be selected to minimize energy requirements and be appropriate for the terrain, whether the RCC is transported by conveyor or haul vehicle. It should be selected to minimize overall haul distances, vertical lift, and exposure of the fresh mixture to sun and

weather. The plant should be located on a raised area so spillage and wash water drain away without creating a muddy area, especially if vehicular haul is used. The plant location for dams will generally be in the future reservoir area just upstream of the dam and above the cofferdam level or on one of the abutments. The plant should have a bypass or belt discharge that allows wasting rejected RCC without first delivering it onto the dam. This bypass can also be used for sampling, for delivery to trial sections, and for other construction uses.

Both continuous mixers and batch mixers have been used to produce RCC; continuous **pugmill** mixers are the most common. Batch operations with drum mixers tend to cause the most difficulties and concerns. They should not be used. For the same space requirements, continuous mixers generally provide greater capacity than batch-type plants. Continuous pugmill mix plants specifically intended for RCC and properly operated and maintained routinely achieve good production rates and uniformity. This applies to plants that operate with volumetric controls as well as to those that operate on weight controls.

Although some RCC has been successfully produced with conventional batch-type plants having drum mixers, problems with low production, bulking, sensitivity to the charging sequence, mixture variability, slow discharge, and buildup in the mixer have been common. This does not mean that acceptable RCC cannot be produced by batch methods and drum mixing, but special attention is needed and low productivity can be expected. Equipment that is well suited to normal high-production conventional concrete is not necessarily suitable for all RCC mixtures and the typically higher production rates.

Roller-compacted concrete mixtures can be very harsh, and some can cause the buildup of fines. Drums should be designed or coated to resist buildup that tends to result from the high fines content of some RCC mixtures. Even with these precautions, experience has shown that substantial buildup can develop in drum mixers. If the buildup is not removed, a loss in mixer effectiveness results. Except for special small applications with higher cementitious contents, clean conventional-type aggregates, and aggregate sizes limited to about 3/4 in., transit trucks and mobile batch plants should be avoided. Even with these types of mixtures, slow discharge and high mixture variability should be anticipated.

Pugmill mixers that were originally intended for cement-treated base, asphalt, or moisture conditioning of soils have presented difficulties with maintenance and variability when they have been used to construct RCC dams; however, pugmill mixers of both the batch and continuous-mix type have performed well when they are specifically designed and intended for RCC. Typical individual plant capacities range from about 150 to over 400 compact cubic meters per hour. It is generally better to have multiple smaller plants than a single larger plant. If one plant is down, the others can usually continue placing while repairs are made. Also, it is easier to find subsequent uses for smaller plants than for very large specialized plants.

The theoretical or rated peak capacity of the plant should be well above the desired average production. As a general guide, the average sustained placing rate usually does not exceed about 65 to 70% of the peak or rated plant capacity when haul vehicles are used for delivery on the dam and 75% when an all-conveyor delivery system is used. These values tend to be lower on smaller projects and higher on uncomplicated larger projects. Table 20.11 shows the average efficiency that can be expected throughout each placement shift for different work schedules and methods of delivery with a properly managed project. These values have increased only a slight amount in recent years compared to early RCC projects.

Mixers for RCC must accomplish two basic functions: They should provide sufficient capacity for the high placing rates typical in RCC, and they should thoroughly blend all ingredients. Typical average placing rates are on the order of about 50 to 150 yd³/hr for small projects, 200 to 500 yd³/hr for medium projects, and 500 to 1000 yd³/hr for large projects. The mixer should operate with little or no downtime. Scheduled maintenance must not be neglected, and repairs should be accomplished rapidly.

Variations in the free-moisture content of the aggregates can be particularly troublesome when the plant starts up. Some plant operators make the error of overestimating free moisture and provide too little water in the initial mixtures. This is particularly undesirable because most initial mixtures will be used for covering construction joints or foundation areas where the RCC should be slightly on the wet side for improved bond. It is better to start on the high side for moisture and subsequently reduce it to the desired consistency than to start with a mixture that is too dry.

TABLE 20.11 Probable Average Sustained Production through Full Shifts

Shifts Worked	Days Worked	All-Conveyor Delivery (%)	Haul on Dam (%)
Two, 10-hour	6 on, 1 off <i>or</i> 12 on, 2 off	76	66
Two, 8-hour			
Three, 8-hour	6 on, 1 off <i>or</i> 12 on, 2 off	73	63
Two, 12-hour			
Three, 8-hour	Continuous up to 28 days	70	61
Two, 10-hour			
Two, 12-hour			
Three, 8-hour	Continuous over 28 days	65	55
Two, 10-hour			
Two, 12-hour			

Note: Assumes Aran continuous pugmill and Rotec or equal proven conveyor. Reduce efficiency by 10% if multiple shifts per day do not overlap. Although Rotec conveyors and Aran mixers (or proven equivalent) may be capable of 80 to 90% efficiency by themselves, the above efficiencies are realistic overall shift values when total maintenance, all types of other equipment breakdowns, aggregate feeding/delivery, raising and moving forms or facings, and slowdowns at abutments are considered.

Mixture uniformity must be maintained for all the production rates used. Continuous mixers typically work efficiently above a minimum production rate and up to production levels that are two to four times that of the minimum rate. A consistently uniform mixture must still be provided even when slowing production by, say, 50% near abutments and when increasing it again after leaving confined areas. Large projects with multiple mixers can simply shut down one or two mixers until the higher production rate is needed again. On smaller projects with one mixer, the mixer must be capable of uniform production at varying outputs. Mixture variability is discussed in more detail in Schrader (1987, 1988, 2003a). Table 20.12 provides a summary of what can be expected with regard to the variability of RCC mixtures at different levels of quality control.

Accurate and consistent control of cement and pozzolan feed is particularly important with continuous-mix plants. This is especially true at lower cement-feed rates. Feeders designed to operate at the high cement-feed rates typical of soil cement or conventional concrete usually do not operate well at the low cement rates required for some RCC mixes. Maintaining sufficient head in the silos, using air fluffers, and using vane feeders or positive-displacement cleated belt feeders have been necessary to provide accurate feed. Proper ribboning or sequencing and feed rates of the aggregates and cementitious material as they are fed into the mixer are critical to minimizing mixing time. Each plant and RCC mixture seems to have its own peculiar requirements that can only be determined by trial and error. Properly designed pugmills have handled 3 in. and larger nominal maximum size aggregate (NMSA), but experience has shown that the amount of material larger than 2 in. should never exceed about 8%, and the maximum size should not exceed 4 in. The preferred NMSA for most mass applications of RCC is 2 in.

Accurately introducing the correct quantities of materials into a mixer is only one part of the mixing process. Uniformly distributing and thoroughly blending them throughout the mixture and then discharging them in a continuous and uniform manner comprise the other part of the process. This can be more troublesome with some RCC mixtures than with conventional concrete mixtures. The accuracy of the concrete plant and methods for control of the mixture during production should be studied for cost effectiveness. If exacting quality control and low variability are necessary, they can be provided in RCC mixtures. Typical coefficients of variation for RCC compression tests are shown in Table 20.12.

20.6.4 Delivery

The volume of material to be placed, access to the placement area, availability of rental or lease equipment, capital cost for new equipment, and design parameters generally are the controlling factors for selection of equipment and procedures to be used for transporting RCC from the mixing location to the placing area. Essentially, the three methods for transporting RCC are by batch, continuously, or

TABLE 20.12 Quality Based on Variability for Roller-Compacted Concrete

Description		Coefficient of Variation				
		Excellent	Very Good	Good	Fair	Poor
Overall	General construction, sampled from the placement	0–11	11–14	14–18	18–23	>23
Within batch	General construction	0–4	4–6	6–8	8–10	>10
Within batch	Lab trial batches	0–3	3–5	5–7	7–9	>9

using a combination of both—typically, via a continuous conveyor feed to a hopper on the dam from which vehicles take batches for final delivery to the spreading area. To some extent, transportation may be influenced by the type of mixing equipment used; however, with proper controls and accessories, such as holding hoppers designed to control segregation, continuous mixers can be used with batch transportation and batch mixers can be used with continuous-flow transportation equipment.

The type of transporting equipment used to move RCC from the mixing plant to the placement area will also be influenced by the largest aggregate size in the mixture. Experience indicates that 1.5-in. NMSA concrete can be transported and placed in nonagitating haul units designed for aggregate hauling and earth moving without substantial uncontrollable segregation. Mixtures with large 3-in. NMSA aggregate have more of a tendency to segregate when they are dumped from this type of equipment onto hard surfaces, but with care and proper procedures these mixtures can be hauled and dumped successfully. Problems with segregation during the transportation and placing of 6-in. NMSA mixtures have been severe. Typical current practice is to require that 100% of the aggregate be smaller than 3 in., with only 1 or 2% allowed above 2 in., and allowing 100% to pass 1.5 in.

The entire system of mixing, transporting, spreading, and compacting should be accomplished as rapidly as possible and with as little rehandling as possible. The time lapse between the start of mixing and completion of compaction should be considerably less than the initial set time of the mixture under the conditions in which it is used. A general rule for nonretarded mixtures with little or no pozzolan is that placing (depositing), spreading, and compacting should be accomplished within 40 minutes of mixing, preferably, within 30 minutes of mixing. This time limit is applicable at mix and ambient temperatures of about 70°F. It can be extended for colder weather and should be reduced in warmer weather. It also can be extended for mixtures that are proven to have extended set times because of high pozzolan contents, slags, or effective admixtures with wet RCC consistencies. A simple test to establish the tolerable time for any particular mix and temperature is to compact two cylinders from the same batch every 15 minutes, beginning immediately after mixing. The cylinders are all tested for compressive strength at the same age, at about 14 or 28 days. A plot of strength vs. time of compaction will quickly indicate the age at which compressive strength becomes seriously affected. Tests have shown that tensile strength and the modulus of elasticity will begin to decrease at about the same time and at the same rate as compressive strength.

The two primary methods of transporting RCC are by conveyor and hauling vehicle. Transport by bucket or dinky has been used, but this slows the rate of production and is more prone to cause segregation; however, if such a system is already available or necessary for large volumes of conventional concrete, it can also be used for the RCC. Pipe delivery has been tried on a few projects with varying degrees of success. If pipe delivery is considered, it should be designed specifically for the mix to be used and potential pressures, it must have a steep slope, the technical issues of moisture loss and temperature gain must be addressed, the length of time in the pipe and its effect on the age of the RCC when compacted must be considered, and sustained satisfactory operation should be proven in full-scale trials.

Transporting RCC by continuous high-speed conveyors directly to the dam is generally preferred. The overall economics, including all direct and indirect costs of alternative delivery systems as well as reliability, the final quality, and schedule should be considered when deciding whether to use or require an

all-conveyor delivery system. All aspects of the conveyor system should be specifically designed for RCC of the type used on the project. The advice of personnel experienced with the type of mixture and equipment proposed should be solicited. Conveyor systems that may work well with conventional structural concrete, aggregates, coal, or other materials may not work well with RCC. Conveyor systems that work well with a high-cementitious-content, wetter, small-aggregate, or no-fines RCC may not work well with a low-cementitious-content, drier, larger aggregate, or high-fines RCC. Clogged transfers, segregation at the discharge, severe wear at transfers, segregation over rollers, slow belts, not being able to start or stop a loaded belt, drying, loss of paste, and contamination of the RCC lift surface by material dropping off the return side of belts are the most common problems. A detailed discussion of conveyor equipment and methods can be found in the literature (Oury and Schrader, 1992).

Where equipment is readily available for lease or rent, an all-conveyor system can be as economical and practical for small projects as it is for larger projects. The 4000-yd³ Echo Lake Dam in California is an example. The project utilized a highway-mobile, all-conveyor delivery system that was driven to the job site and erected in one day. It was used the next two days for RCC placement where haul units could not possibly work and was then driven off to the next project. It was fed from an equally mobile RCC continuous-mix pugmill.

A written agreement stating that the schedule and design are based on a required predeveloped conveyor delivery system is an approach that can be used at the time of the design so the engineer can confidently base the design on the better quality, cleaner, and faster lifts placed by specialized RCC conveyors, rather than relying upon the slower production and lower quality lift surfaces typical when haul vehicles are used on the surface. The supplier guarantees availability of the equipment, the required production capability, “not to exceed” reasonable downtimes, and availability of field technicians to assist the contractor. The supplier also guarantees a “not to exceed” price that will be quoted to all qualified bidders. The agreement should address an appropriate allowance for downtime and on-site spare parts.

Allowance is made for contractors to submit a more elaborate conveyor system, whereby, at their option, their costs may be greater but they purchase rather than lease the equipment or they achieve faster production rates. This approach has been used on public projects in at least two countries, with legal documents being created that satisfy all public entities as well as the designer, supplier, and contractors. This approach has proven to be good for owners, designers, and contractors. It reduces risk, ensures a low, preestablished cost, guarantees placement methods that are compatible with design, and helps maintain the planned construction schedule.

All-conveyor delivery systems can be supported and arranged in several ways. One approach that has been used for many years, including on projects such as the Cuchillo Negro Dam, Lake Robertson Dam, Loyalty Road Dam, and others, utilizes vertical posts embedded in, and raised with, the dam to support and raise the conveyors. Conveyors reach from the posts to essentially anywhere on the dam surface. Seigrist and Spring Hollow Dams are examples where conveyors were used that were supported from smaller pipe posts anchored to the upstream face of the dam with a long conveyor that extended the full length of the upstream face of the dam and that raised with the dam. This approach was successful, but the procedure has not become popular because other methods have been more effective and adaptable to changing field conditions. The conveyor feeds a tripper that runs along the main belt at the upstream face to feed a crawler-mounted mobile conveyor placer on the lift surface. The crawler placer can drive on the surface, extend or retract its conveyor, lift it, or swing it similar to the boom on a hydraulic crane. This allows the operator to deposit the RCC in a layer at its final location. Smoothing the layer with a bulldozer and compaction can follow immediately after the RCC has been deposited from the conveyor. A similar procedure was used for much of the San Rafael Dam in Mexico. The crawler placer, with a different setup for the conveyors that fed to it, was used at Concepcion Dam in Honduras and is being used at the Pangué Dam in Chile and other RCC dams.

For Echo Lake and Big Haynes Dams, wheel-mounted conveyors, called *creter cranes*, and swingers reached from outside the dam to the lift surface to deposit the RCC in layers; however, this method is only suitable for small dams or for the smaller upper abutment portions of larger dams, as was done at Burnett River Dam. Burton Gorge Dam in Australia utilized a partial conveyor system with a belt feeding

FIGURE 20.49 Tower belt with 320-ft reach at Miel I dam in Colombia.

continuously from a pugmill mixer to a hopper on the dam. Trucks then hauled the RCC from the hopper to the placing area. Problems with this type of system include continual raising of the hopper, segregation at the edges of each load dumped into and out of the trucks, damage to the surface caused by the truck tires, and insufficient room at the top of the dam for the hopper and trucks.

Large dams now typically use a *tower belt*. The largest towers may stand more than 200 ft above the surface of the dam and raise with it. They also can reach as high as 300 ft. The tower supports a horizontal boom with a line and hook that virtually hang a large conveyor out in space, or it can be used to lift very large loads at long reaches when used as a traditional crane. The tower itself can also be rigged to support connected segments of conveyor belt in space, leaving the crane available for other tasks. The conveyor belts typically feed a large *crawler placer*. This equipment is essentially a crawler-mounted crane with another belt for a boom. The belt can extend in or out, swing left or right, and angle up or down to deposit RCC in even windrows at essentially any location on the dam. Within a couple minutes of mixing, fresh RCC is typically delivered and placed on the dam with this type of system at rates ranging from about 200 to 1000 yd³/hr. The Miel I dam in Colombia is one example (Figure 20.49). Exposure time on conveyors should be as short as practical, with a maximum typically of about 5 minutes. Belt speeds should be on the order of about 10 to 30 ft/sec. Covering the conveyor to protect the mixture from drying and from rain should be required for all long sections and preferably for the entire system.

A well-designed conveyor system can also be capable of handling conventional concretes concurrently with RCC; however, this may complicate the placing operation unless separate parallel conveyors for the RCC and conventional concrete are provided. On the Elk Creek project, a larger belt was used for RCC while a parallel smaller one was used for conventional concrete, bedding mixes, facing mixes, and grout. It is especially important that conveyors do not allow RCC or other material to fall onto the compacted RCC surface along the conveyor path. Because of the rapid rise of RCC dams, conveyor systems should

FIGURE 20.50 RCC production in confined work areas.

be designed to be raised quickly. When conveyors are located above the lift surface, provision must be made for clearance of equipment operating under them.

As with conventional mass-concrete conveyor systems, special attention should be given to belt widths, speed, protection, maintenance, incline angles, backup systems, and spare parts. Belt scrapers should be provided to clean return belts, which typically require frequent attention for adjustment and wear. Special attention is necessary to prevent segregation at transfer points and at any interim hoppers or bins.

A continuous belt running from the mixer to the final placement area can substantially increase placing rates and significantly reduce other equipment needs and their related labor requirements. Figure 20.50 compares typical average achievable productivities for reduced dam widths when delivery is totally by conveyor and when haul vehicles are used on the dam. Without a conveyor, productivity decreases to very low rates in narrow sections such as at the top of a dam. Figure 20.50 is based on a compilation of actual data at various projects and from computed round-trip delivery times at other projects.

In addition to the benefits of full-conveyor delivery (no hoppers, fast delivery, less congestion, no haul roads, less maintenance, less labor, elimination of lift-surface damage from haul vehicles, and improved productivity), the conveyor can also serve as an access walkway and as a support for lights, water, air, and electric lines to the placement area. A plan has even been developed to use the conveyor as a support for a roof or enclosure to protect the placement area from rain, sun, and wind.

When haul units are used to distribute RCC that is conveyed to the lift surface, a hopper arrangement that continuously loads them will be necessary at the end of the main conveyor. The objective is to allow the mixers and conveyors to operate and discharge without interruption or waiting for haul vehicles. The recommended minimum size of the hopper is at least twice the size of the haul vehicle. Because of the relatively high unit weight of freshly mixed RCC compared to the loose unit weight of soil, rock, or gravel normally hauled in these vehicles, weight rather than volume normally controls the amount of material hauled per trip. Bottom-dump trailers and scrapers minimize segregation, spreading requirements, and the distance the RCC drops, but they are difficult to use near abutments and obstructions. Scrapers have

better mobility than bottom-dump trailers of the highway type. Scrapers and bottom-dumps trailers have the advantage of depositing material in the layer to be spread as they are moving. This was common method of placement in some early RCC projects, but it has lost favor to large articulated trucks with special tailgates that minimize segregation or to all-conveyor delivery.

Front-end loaders have been used to deliver RCC from a central feed point on the placement to the location where it is spread. This is generally not suitable and should not be done on large projects or in critical areas. The method has resulted in problems with contamination of joint surfaces, limited productivity, and segregation. In special cases, however, where the mixture is not susceptible to segregation, spillage can be avoided, and tire tracking is not a problem, this method may result in the most economical situation that is also technically acceptable. Principle candidates for this approach are smaller dams in tight canyons where the distance for loader travel is minimal. Also, the projects should preferably have a smaller maximum size aggregate, excellent gradation, and a tendency for a higher paste and cementitious content. In addition, each layer should be placed and compacted before the set time of the previous layer. Extra cleaning or special grout or bedding mixtures may be appropriate between layers when they are not placed and compacted before the previous layer reaches its final set. If vehicles are to be used for transporting RCC, a thorough study should be made of the haul route. Problems that may prevent hauling by road include steep and rough terrain, availability of road-building material, plant location, schedule, and environmental considerations. If the concrete plant is located upstream of a dam, it may not be practical to bring the road through or over the upstream face system. Raising the roads to keep up with the rate of rise of the dam may require so much time that it becomes an inefficient system at higher elevations. To avoid slowing down the mixing and placing operations, raising the roads during a 2- to 4-hr/day shutdown period while maintenance and other work is being done should be considered. Roads must be kept at slopes consistent with the capabilities and safety requirements of the equipment.

Haul roads should make the transition onto the lift surface at a shallow angle if possible (plan view) so turning and damage by tires are minimized. If an immediate right-angle turn is necessary (from roads that enter directly onto the dam perpendicular to the face), significant scuffing and lift-surface damage will result. Operators should move slowly while turning and use the largest turning radius possible. The road should be constructed with clean, free-draining rock or gravels, if possible.

The last portion of the road prior to entering the lift should be surfaced with large aggregate or clean rock material that minimizes contamination of the RCC surface from truck tires. Simply extending the RCC onto the road will not provide cleaning action. To prevent lift contamination, it may be necessary to use water sprays to wash vehicle wheels before they are allowed on the lift surface, but excess water dripping from the truck and its tires can become a problem. To minimize adverse effects on the surface, hauling equipment should not travel in a concentrated path on the lift. Even with all of the above precautions, experience, including observation and cores, has shown that damaged lift surfaces should be expected where haul roads onto the dam are used.

When the RCC is hauled to the placing location and dumped, it should generally be deposited on previously spread but uncompacted material and pushed forward onto the compacted lift surface. This provides remixing action and minimizes clusters of coarse aggregate that otherwise would tend to occur at the lift interface. When RCC is dumped in large piles, larger aggregates tend to roll down the outside of the piles and create clusters. A general rule is to limit the height of a pile to 5 ft. Correcting this kind of segregation is nearly impossible if the rock has already rolled onto a previously compacted lift. Where this condition occurs, the segregated large aggregate must be removed, broadcast onto the RCC layer being spread, or wasted.

20.6.5 Placing and Spreading

A preferred technique for placing RCC is to advance each lift from one abutment to the other. An exception is where the distance from abutment to abutment is smaller than the distance from the upstream to the downstream face, such as at the bottom of dams in narrow canyons. In this case, placing can begin by working in the upstream–downstream direction. Large dams, where the distance from abutment to

abutment is long and where all of the foundation may not be ready at the time RCC placement starts, can benefit from placing between forms within any group of monolith blocks if the area is large enough for efficient production. This will also reduce the time of exposure of each lift, thereby improving lift-joint quality. The practice from embankment construction of limiting the direction in which rolling equipment can operate does not apply to RCC.

Some early RCC projects considered, recommended, approved, or required placing RCC in paving lanes, typically going from abutment to abutment. This initially seemed like a logical approach, but the practice is now discouraged or prohibited. The problems with it are more serious with low-cementitious-content, dry-consistency, and large aggregate mixtures. Although they may work well with paving mixtures and paving operations, spreader boxes attached to dump trucks, Jersey spreaders attached to dozer equipment, and paving machines lack mobility and occupy important space in narrow areas of the dam. They can be difficult to maneuver at the abutments. Paving lanes tend to leave segregation along the edge of the lanes with dam mixtures. The edges can also become too old to be well mixed and compacted into RCC of the adjacent lane by the time the adjacent lane is placed. The edge also tends to dry out while exposed prior to placing the adjacent lane. This has resulted in concerns over poor quality and weakened or permeable planes through the dam at the interface of paving lanes. For a high-cementitious-content mix with smaller aggregate, a wetter consistency, and a retarded set time, concerns about placing using pavement lanes are reduced.

Tracked dozer equipment has proven to be best for spreading RCC. It is fast and sufficiently accurate and contributes to uniformly compacted RCC. By careful spreading, a bulldozer can remix RCC and minimize segregation that results from dumping. Careful attention should be given to ensure that remixing is occurring and that the dozer is not simply burying segregated material. At Elk Creek Dam, retarded RCC mixtures with a Vebe time of 15 to 25 sec were end dumped in piles at least 35 ft from the advancing face. Dozers knocked down the piles and spread the RCC forward into thin, unsegregated, 6-in.-thick layers until a full lift thickness of 24 in. was reached. The entire surface of each layer was traversed by at least two passes of the dozer tracks. This dozer action produced an average density of 147 pcf. Only the top of the 24-in. full thickness of the lift then required additional compaction by the roller. Similar results have been achieved with other RCC mixtures having a wet mixture consistency. At Nickajack Dam, wet-consistency, air-entrained RCC was spread in two 12-in.-thick layers, with the second layer following behind the first layer. The second layer was compacted before the first reached initial set. The advancing layer was about 100 ft in front of the following layer.

At Burton Gorge Dam in Australia, 100% compaction was achieved using a small dozer in the top portion of the dam by modifying the mixture with retarder, using a wetter consistency, placing rapidly (one lift every 1 to 4 hours), and rigorously tracking the 12-in.-thick layers as they were spread. This resulted in densities that reached the theoretical air-free density of the mixture. Thorough dozer tracking the same mixture at a dry consistency and without retarder, but while the mixture was less than about 30 minutes old, achieved densities on the order of about 96% of the theoretical air-free values. This was followed by roller compaction to achieve a higher final density.

Typically, two rollers and one D6 dozer with a backup smaller dozer can spread and roll nonretarded RCC at a rate of about 300 to 500 yd³/hr in 12-in.-thick layers. The dozer should operate on fresh RCC that has not been compacted. All turning and crabbing should be done on uncompacted material. Operating the dozer on a compacted surface will damage the surface, unless the dozer is equipped with rubber tracks and the operator uses special care. Recently a device has been developed with rubber tires that attaches to the dozer. The device is lowered to lift the tracks off the surface so the dozer can drive across the RCC from one end to the other without causing damage. When it is necessary for the dozer without this device to drive onto compacted RCC, the operator should limit the movement to straight back-and-forth travel. Track marks made prior to the mixture reaching initial set can be recompacted by the vibratory roller without significant loss of joint quality; however, damaged surfaces that are recompacted after the mixture has set or if it has dried will have little or no strength, even though they may have acceptable surface appearance. Damaged material can be easily removed by blowing with an air jet, even many hours later. Material that is recompacted early enough will remain cemented in place if blown with an air jet.

A relatively recent development in RCC spreading is the *slope-layer method*. Starting from a previous level lift surface, the RCC layer is placed on a slope of about 10 (H):1 (V), more or less. The first layer is then just a small fillet of RCC. A second layer is immediately placed over this at the same slope followed by a third, fourth, and subsequent layers, until the vertical depth of the multiple layers at the high end is some preestablished height on the order of about 6 ft, more or less. This becomes the total lift height for the multiple layers. Because of the slope of the layers, the length of each layer is minimized. In the case of a 10 (H):1 (V) slope and 6-ft lift depth, the distance is only 60 ft. This allows each layer to be placed before the subsequent layer approaches its setting time. Lift-joint cleaning is not really required except when contamination is an issue, and the layers will bond together in one mass without noticeable layer joints lines. The final top surface requires special attention afterward for cleanup before starting the next lift of multiple layers. The procedure must be coordinated with forming and form supports, so it has places where it is beneficial and places where it is not advantageous.

Spreading equipment should leave a flat or plane surface of the proper thickness before the roller does its compaction. The roller should not bridge over high points and miss providing full compaction at low points of freshly spread lift surface. Depending on the workability of the mixture, ridges or steps between adjacent passes of the dozer blade can result in uneven compactive efforts and variable quality in the RCC. As a general rule, having a flat surface ready to roll in the least amount of time is more important than having an exact grade with delayed rolling. Typical tolerances for lift thicknesses are on the order of ± 2 in., except for the exposed final lift surface in a structure, which typically has a much smaller tolerance.

Where special mixtures are specified (e.g., at the upstream or downstream face), special procedures are required. If conventional concrete is used against a formed face with a dry-consistency RCC mass behind it, the conventional mixture should be placed first and the RCC immediately spread against and on top of the sloping unformed face of the conventional concrete. The conventional mixture should be designed to lose slump rapidly but not set rapidly. This allows the RCC to be compacted into the conventional concrete before either mixture sets. If the conventional concrete does not lose slump soon enough, the roller will sink into it resulting in a variety of construction problems. If rolling is delayed while waiting for the conventional mixture to stiffen, the RCC can become too old for proper compaction. If the roller operator simply stays back from the conventional concrete far enough to avoid sinking into it or shoving it up, the two mixtures will not adequately compact or join together. Using more of the conventional concrete makes the problem worse. Usually, only 12 in. of conventional concrete is used, but some projects have been successful with only a few inches of facing. If the facing concrete is wider than about 18 in., the mixture is usually consolidated with immersion-type vibrators while the adjacent RCC is rolled.

If the RCC has a wetter consistency, and especially if it has a delayed set, it is possible to place the conventional concrete mixture after the RCC. The facing concrete still needs to have a relatively low slump when RCC compaction is performed, but it can still be possible to immersion vibrate the interface region of the RCC and conventional concrete. With this procedure, the width of conventional concrete has typically been wider than when conventional facing mixtures are used with drier consistency RCC; however, experience, coring, and internal destructive investigations have shown that a poor interface of the two mixtures has often resulted with this procedure, even when the two mixtures appeared to respond well to immersion vibration and the exposed top surface of the layers looked well consolidated.

The most common compacted lift thickness has been 12 in. Typically, large, dual-drum vibratory rollers can develop full compaction of this thickness with only four to five passes. A factor influencing lift thickness is the maximum allowed exposure time before covering one lift with the subsequent lift. Each project should be studied to optimize the benefits of thicker or thinner lifts. Thicker lifts mean longer exposure times but fewer lift joints and fewer potential seepage paths. Thinner lifts result in more potential joints but allow the joints to be covered sooner with better bonds.

At the start of extremely rough foundations and where the foundation has deep holes that have not been filled with dental or leveling concrete, a front-end loader or excavator bucket can sometimes be used to reach the placement site to deposit material. This is a slow operation but may be the only practical

solution for some locations. The problem is eliminated with the all-conveyor delivery system or with mobile conveyors that reach across and into areas of rough terrain.

The equivalent of a Cat D-4 Case 550 rubber track or a JD-450 is required to start the foundation and for tight conditions. With an all-conveyor delivery system, a Cat D-4 is generally capable of spreading RCC at a rate of about 300 yd³/hr. Dozers should have hydraulic tilt and angle capability. It is common to underestimate the value of good spreading equipment and operators. Graders have been used on some RCC projects, but they generally are not necessary and can actually become a problem. They are difficult to maneuver in small areas, and the tires can damage otherwise good compacted surfaces. There also is a tendency to overwork and rework the surface as if it were soil instead of concrete with a limited working time.

20.6.6 Compaction

Maneuverability, compactive force, drum size, frequency, amplitude, operating speed, and required maintenance are all parameters to be considered in the selection of a roller. The compactive output in volume of concrete per hour obviously increases with the physical size and speed of the roller, but larger size rollers do not necessarily give the same or better density and compactive effort as smaller rollers with a greater dynamic force per unit of drum width. Job size, workability, lift depth, the extent of consolidation due to dozer action, and space limitations will usually dictate roller selection. Large rollers cannot operate closer than about 6 in. to vertical formwork or obstacles, so smaller hand-guided compaction equipment is usually required to compact RCC in these areas. If a slipformed or precast facing system that has an interior face sloping away from the RCC is used, the large rollers can operate all the way to the facing.

The dynamic force per unit of drum width or per area of impact on tampers is the primary factor that establishes effectiveness of the compaction equipment. Most experience has also shown that rollers with a higher frequency and lower amplitude compact RCC better than rollers with high amplitude and lower frequency, although suitable results have been achieved on some projects using rollers with both high frequency and amplitude. The typical compactor is a 10-ton double- or single-drum roller with a dynamic force of at least 475 lb of force per inch of drum width. These rollers are typically used for asphalt and roadway compaction. Larger 15- and 20-ton rollers of greater mass and size, typically used with rockfill construction, have been used with RCC, but they usually have larger amplitudes and lower frequency and are less suited to the aggregate gradings used in RCC. Achieving density and a good lift-joint interface is more difficult with these larger rollers.

In tight areas such as adjacent to forms and next to rock outcrops, large tamping foot-type compactors are most suitable. They are mobile and can provide high-impact energy to produce good density; however, they usually do not leave a smooth surface and they can sink when tamping RCC that has been placed over an excessive thickness of wet bedding mixture, when tamping RCC with excess water, or when tamping next to a conventional concrete mixture that has not lost its slump. One-man vibrating plate compactors intended for sands are not very effective, but the more recent massive plate compactors intended for deep lifts of gravel are effective, although they may require multiple passes. Walk-behind rollers are not very effective in most cases unless they can produce a dynamic force on the order of about 250 lb/in. of drum width. Four to six passes of this type roller on fresh RCC not deeper than 12 in. usually results in suitable compaction for tight areas, with densities about 98% of those achieved with the large roller. This reduced density is often considered acceptable, except for special areas that are identified as critical and truly in need of greater compaction.

The appearance of fully compacted RCC is dependent on the mixture proportions. Mixtures of wetter consistency usually exhibit a discernible pressure wave in front of the roller. If the paste content is equal to or less than the volume required to fill all the aggregate voids, rock-to-rock aggregate contact occurs and a pressure wave may not be apparent. This can also occur if the mixture is simply too dry to develop internal pore pressure under the dynamic effect of the roller. Mixtures that have more paste than necessary to fill aggregate voids and a wetter consistency will result in visible paste at the surface that may pick up

on the roller drum, depending on the constituents and plasticity of the paste. The fresh mixture surface should be spread in such a way that the roller drum produces a consistent compactive pressure under the entire width of the drum. If the uncompacted lift surface is not reasonably smooth, the drum may overcompact high spots and undercompact low spots.

Minor damage from scuff marks and unavoidable dozer tears in the surface of a freshly compacted lift can usually be immediately rolled down with the vibratory drum in a static mode or with a rubber tire roller. If the mixture was sufficiently fresh and moist when rerolled, a suitable rehabilitation of the damage will result. If the mixture is too old, severely damaged, etc., the rerolled RCC may look acceptable, but it can and should be easily blown off by an air hose used for general cleanup of loose debris on the lift. For sliding stability, joint tension, or watertightness, designs usually require clean and relatively fresh joint surfaces with good bond. This is typically achieved by the use of a suitable large vacuum truck or air blowing. Some tests have shown sandblasting at 24 and 72 hr can actually reduce bond.

20.6.7 Joint Treatment and Inspection

Lift-joint damage from free surface water (rain or overcuring) was discussed in Section 20.3.4 as it relates to the different types of RCC mixes (i.e., wetter or drier consistency and inspection). Lift joints should be kept from drying or freezing continuously, 24 hr per day, 7 days per week, prior to the next layer of RCC. Tests and experience have shown, however, that allowing the surface to dry back to just under an SSD condition, as indicated by a change in color from darker to lighter, will greatly facilitate cleaning by air blowing and will not reduce joint quality for most RCC. Some tests have even shown a slight increase in joint strength. Rewetting the surface after final cleaning and just prior to spreading RCC over it is considered prudent. In addition to the benefit of cure, keeping the surface from drying out provides evaporative surface cooling, thus reducing internal temperatures and providing a lower joint maturity value. If the surface is more than about 2 days old and it has become sufficiently hard, water washing may be necessary if air blowing alone does not adequately clean off any damage, contamination, and general laitance that may be present. Water washing can only be used after the surface has hardened. Sandblasting is generally not advised or necessary.

Roller-compacted concrete mixtures generally do not bleed or develop laitance at the surface. An exception is very wet mixtures and some cases of dry mixtures after days of moist cure. If there is no weak laitance or other contamination at the surface, the lift-joint cleaning typically required with conventional concrete is not necessary. Although it is the subject of some debate, minor intermittent laitance that may occur in some situations is generally not removed.

If the construction joint is less than about 1500°F degree-hr old and if it has been kept clean and moist throughout its exposure, no joint treatment is required under most conditions. If the surface has been contaminated by dirt, mud, or other foreign elements, the contamination should be removed. The degree-hr maturity is the sum of the temperatures of the lift surface measured every hour during the time that it is exposed. If the surface has been allowed to dry out, exceed about 1500°F degree-hr of maturity, or became damaged, it should be cleaned and may require a full or partial bedding mixture prior to placement of RCC. The 1500°F degree-hr used here is an example. It may be 900 at one project and 2100 at another. These variables make specifications for RCC lift surfaces difficult to write, and they leave inspection of this most critical item to the judgment of both the designer and contractor.

20.6.8 Curing and Weather Protection

After the RCC has been placed and compacted, the lift surface must be cured and protected, just as for concrete placed by conventional methods. The surface must be maintained in a moist condition, or at least so moisture does not escape. It should also be protected from temperature extremes and freezing until it gains sufficient strength. When haul vehicles are used on the lift surface, RCC placement typically must immediately stop with even the slightest rainfall; otherwise, the tires will turn the surface into a soft damaged material that then will require waiting for the RCC to harden so extensive cleanup can be

undertaken. When conveyors are used for delivery and little or no vehicular traffic is required on the RCC, construction can continue in slight rainfall. This may require a gradual and very slight decrease in the amount of mixture water used because of the higher humidity and lack of surface drying. Table 20.3, based on data covering various types of mixes and delivery methods throughout the world over the past 15 years, provides guidance with regard to the effect of rain on RCC placing operations. Immediately after an RCC lift has been compacted, it is essentially impermeable and will not become damaged by light to moderate rain if there is no hauling or traffic on the surface. After a rain, hauling on the lift can resume only after the surface has begun to dry naturally to a SSD condition. A slightly sloped surface will aid in draining free water and speed resumption of placing operations.

Cure during construction has been accomplished with modified water trucks on larger projects and with hand-held hoses for all size projects. Trucks should be equipped with fog nozzles that apply a fine mist that does not wash or erode the surface. Trucks can be augmented with hand-held hoses that reach areas that are inaccessible to the water truck. Provision must be made for maintaining the damp surface while the trucks are fueled, maintained, and refilled with water. Care should be exercised that the trucks do a minimum amount of turning and minimally disrupt the surface. Maintaining access on and off every lift during construction can be a problem that makes trucks impractical; consequently, the recent trend has been to use hand-held hoses rather than water trucks.

The final lift of RCC should be cured for an appropriate time, generally in excess of 14 days. Curing compound is unsuitable because of the difficulty in achieving 100% coverage on the relatively rough surface, the probable damage to the surface from construction activity, the low initial moisture in the mixture, and the loss of beneficial surface temperature control that is associated with moist curing. Unformed sloping surfaces such as the downstream face of a dam are very difficult to compact and can be considered sacrificial and unnecessary to cure provided this has been incorporated into the design. Uncompacted exposed RCC will be subject to raveling. Whereas the outside several inches will be incapable of achieving any significant strength or quality, they will serve as protection and a moisture barrier for the curing of the interior RCC.

Defining Terms

Abutment—The foundation along the sides of the valley or gorge against which a dam is constructed.

Autogenous volume change—The change in volume produced by continued hydration of concrete exclusive of effects external forces, water changes, and temperature changes.

Cementitious material—The fine solid-particle material in concrete that reacts in solution with water and at times other fine solid particles to create a hardened concrete with strength; Portland cement, sometimes with pozzolan, is usually used.

Coefficient of thermal expansion—The change in linear dimension per unit length divided by the temperature change.

Cohesion—The adhesion of concrete or mortar to other concrete, rock, and other materials.

Creep—Deformation over a long period of time under a continuous sustained load; also, the relaxation or reduction of stress over a long period of time under a sustained deformation.

Durability—The ability of concrete to resist weathering action, chemical attack, abrasion, and other service conditions.

Gallery—A long, narrow passage in a dam or concrete mass used for access, inspection, grouting, drilling drain holes, and collecting seepage.

Grout curtain—A row of holes filled with grout under pressure near the heel of a dam to control seepage under the dam.

Heat of hydration—Heat generated by chemical reactions of cementitious materials with water, such as the heat evolved during setting and hardening of Portland cement.

Lift-joint quality index (LJQI)—A numerical designation indicating the quality of a concrete lift joint, derived from evaluation of the factors affecting the quality of the joint.

Modulus of elasticity (elastic modulus)—The ratio of stress to strain in the elastic region of behavior prior to development of nonrecoverable microfracturing.

Monolith—A section or block of a large structure such as a dam that is bounded by free faces or contraction joints.

Paste—That portion of a fresh concrete mixture that is composed of a mixture of all particles that will pass through a No. 200 or 75- μm sieve (namely, cement, pozzolan or fly ash, water, small air bubbles, admixtures, and aggregate fines).

Permeability—The rate of flow of water through a unit cross-sectional area under a unit hydrostatic gradient.

Poisson's ratio—The ratio of transverse strain to axial strain resulting from a uniformly distributed axial stress.

Pozzolan—A finely divided powder that is composed of siliceous and other minerals that react with the byproducts of Portland cement hydration to form additional cementitious materials.

Principal stress—Maximum and minimum stress occurring at right angles to a principal plane of stress.

Pugmill—A mixing chamber usually composed of two horizontal rotating shafts to which mixing paddles are attached.

Restraint—Internal or external restriction of free movement of concrete in one or more directions.

Roller-compacted concrete (RCC)—A relatively dry concrete mixture that can be compacted by vibratory rolling, usually by a 10-ton roller.

Sustained modulus of elasticity—The modulus of elasticity of concrete that occurs under constant sustained load, including the effects of creep.

Theoretical air-free density—The density corresponding to a concrete that has been compacted to 100% solids with no air.

Ultimate modulus—The ratio of stress to strain that occurs at the maximum load beyond which concrete loses strength and fails.

21.1 Introduction

Concrete differs from other construction materials in that it can be made from an infinite combination of suitable materials, and its final properties depend on the treatment it undergoes after it arrives at the job site. The efficiency of the consolidation and the effectiveness of curing procedures are critical for attaining the full potential of a concrete mixture. Although concrete is known for its durability, it is susceptible to a range of environmental degradation factors that can limit its service life. There has always been a need for test methods to measure the in-place properties of concrete for quality assurance and for evaluation of existing conditions. Ideally, these methods should be nondestructive so they do not impair the function of the structure and also permit retesting at the same locations to evaluate changes in properties with time.

Compared with the development of nondestructive test (NDT) methods for steel structures, the development of NDT methods for concrete has progressed at a slower pace, because concrete is inherently more difficult to test than steel. Concrete is highly heterogeneous, it is electrically nonconductive but usually contains significant amounts of steel reinforcement, and it is often used in thick members. Thus, it has not been easy to transfer NDT technologies developed for steel to the evaluation of concrete. In addition, there has been little interest among those from the traditional NDT community (physicists, electrical engineers, mechanical engineers) to develop test methods for concrete. Since the 1980s, however, advances have

Break-off	Nuclear methods
Maturity method	Infrared thermography

occurred as a result of the microcomputer revolution and the development of powerful signal-processing techniques. No standard definition exists for **nondestructive test** as applied to concrete. For some people, it is any test that does not alter the concrete. For others, it is a test that does not impair the function of a structure, in which case the drilling of cores is considered to be a NDT test. For still others, it is a test that does less damage to the structure than does drilling of cores. This chapter deals with methods that either do not alter the concrete or that result in only superficial local damage. The author prefers to divide the various methods into two groups: (1) those whose main purpose is to **estimate in-place strength**, and (2) those whose main purpose is to evaluate conditions other than strength—that is, to **evaluate integrity**. It will be shown that the most reliable tests for strength are those that result in superficial local damage, and the author prefers the term **in-place tests** for this group. The integrity tests, on the other hand, are truly nondestructive.

The purpose of this chapter is to provide an introduction to commonly used NDT methods for concrete. Table 21.1 lists the various test methods that are considered here. Emphasis is placed on the principles underlying the various methods so the reader may understand their advantages and inherent limitations. Additional information on the application of these methods is available in ACI 228.1R (ACI Committee 228, 2003), ACI 228.2R (ACI Committee 228, 1998), Malhotra and Carino (2004), and Bungey and Millard (1996). Portions of this chapter are based on previously published works of the author (Carino, 1992a, 1994).

21.2 Methods to Estimate In-Place Strength

21.2.1 Historical Background

Some of the first methods to evaluate the in-place strength of concrete were adaptations of the Brinell hardness* test for metals, which involves pushing a high-strength steel ball into the test piece under a given force and measuring the area of the indentation. In the metals test, the load is applied by an hydraulic loading system. Modifications were required to use this type of test on a concrete structure. In 1934, Professor K. Gaede in Germany reported on the use of a spring-driven impactor to supply the force to drive a steel ball into the concrete (Malhotra, 1976). A nonlinear, empirical relationship was obtained between cube compressive strength and indentation diameter. In 1936, J.P. Williams in England reported on a spring-loaded, pistol-shaped device in which a 4-mm ball was attached to a plunger (Malhotra, 1976). The spring was compressed by turning a screw, a trigger released the compressed spring, and the plunger was propelled toward the concrete. The diameter of the indentation produced by the ball was measured with a magnifying glass and scale.

In 1938, a landmark paper by D.G. Skramtajev, of the Central Institute for Industrial Building Research in Moscow, summarized 14 different techniques for estimating the in-place strength of concrete, 10 of which were developed in the Soviet Union (Skramtajev, 1938). This paper should be read by every student

* The term *hardness* is used routinely in the description of a series of tests of metals and concrete, yet this is not a readily quantified mechanical property. If one considers the nature of the hardness test methods that have been developed for metals, it can be concluded that these tests measure the amount of penetration caused by a specific indenter under a specific load. Therefore, a more descriptive term for these methods might be *indentation* tests.

of nondestructive testing for its historical content. Skramtajev divided the test methods into two groups: (1) those that required installation of test hardware prior to placement of concrete, and (2) those that did not require preinstallation of hardware. The methods described by Skramtajev included the following:

- Molds placed in the structure to form in-place test specimens
- Pullout tests of embedded bars
- An in-place punching shear test
- An in-place fracture test using a pincer device
- Penetration with a chisel driven by hammer blows
- Guns that fired indenters into the concrete
- Penetration with a ball powered by a spring-driven apparatus

Readers who are familiar with modern in-place test methods (to be discussed later) will recognize that many of them are variations of methods suggested more than 70 years ago. Skramtajev also commented on the need for in-place testing. For example, he noted that (Skramtajev, 1938):

- The curing conditions of standard test specimens are not representative of the concrete in the structure.
- The number of standard test specimens is insufficient to ensure the adequacy of all members in a structure.
- Standard test specimens that are tested at an age of 1 month provide no information on the later-age strength of concrete in the structure.
- Surface tests may not provide an indication of the actual concrete strength due to the effects of carbonation, laitance, and moisture condition.
- Methods requiring preplacement of hardware tend to provide more precise estimates of strength than those that do not require preplacement of hardware, but they lack flexibility for use at any desired location in an existing structure.

It is interesting to note that the same arguments and limitations are quoted today in relation to in-place testing (ACI Committee 228, 2003).

21.2.2 Rebound Hammer

In 1984, Ernst Schmidt, a Swiss engineer, developed a device for testing concrete based on the rebound principle (Malhotra, 1976, 2004). As was the case with earlier indentation tests, the motivation for this new device came from tests developed to measure the hardness of metals. In this case, the new device was an outgrowth of the Scleroscope* test, which involves measuring the rebound height of a diamond-tipped hammer, or mass, that is dropped from a fixed height above the test surface. As noted by Kolek (1958), when concrete is struck by a hammer, the degree of rebound is an indicator of the hardness of the concrete. Schmidt standardized the hammer blow by developing a spring-loaded hammer and devised a method to measure the rebound of the hammer. Several different models of the device were built (Greene, 1954), and Figure 21.1 provides a schematic of the model that was eventually adopted for field use. The essential parts of the Schmidt rebound hammer are the outer body, the hammer, the plunger, the spring, and the slide indicator. To perform the test, the plunger is extended from the body of the instrument, which causes a latch mechanism to grab hold of the hammer (Figure 21.1a). The body of the instrument is then pushed toward the concrete surface which stretches the spring attached to the hammer and the body (Figure 21.1b). When the body is pushed to the limit, the latch is released and the hammer is propelled toward the concrete by a combination of gravity and spring forces (Figure 21.1c). The hammer strikes the shoulder of the plunger and it rebounds (Figure 21.1d). The rebound distance is measured on a scale by a slide indicator. The rebound distance is expressed as a *rebound*

* In Greek, the word *sklero* means “hard.”

FIGURE 21.1 Schematic cross-sectional view of rebound hammer showing principle of operation.

number, which is the percentage of the initial extension of the spring (Kolek, 1958). Currently, the various models of the instrument that are available differ in the mass of the hammer and the stiffness of the spring; thus, different impact energies can be used for different materials.

Due to its simplicity and low cost, the Schmidt rebound hammer is by far the most widely used nondestructive test device for concrete. Although the test appears simple, there is no simple relationship between the rebound number and the strength of concrete. In principle, the rebound is affected by the small penetration (elastic and inelastic) of the end of the plunger in contact with the concrete. The more the end of the plunger penetrates, the lower is the rebound; thus, the rebound number is likely to be influenced by the elastic stiffness and the strength of the concrete. Because the rebound number is indicative of the near-surface properties of the concrete, it may not be indicative of the bulk concrete in a structural member. The report of ACI Committee 228 (2003) outlines some of the factors that may result in rebound numbers that are not representative of the bulk concrete. They include:

- The moisture condition of the surface concrete affects the rebound number; a dry surface results in a higher rebound number.
- The presence of a surface layer of carbonation increases the rebound number.
- The surface texture affects the rebound number, with smooth hard-troweled surfaces giving higher values than rough-textured surfaces.
- The rebound number is affected by the orientation of the instrument in relation to the direction of gravity (approximate correction factors are available).

Because the rebound number is affected by the near-surface conditions, erratic results may occur if the plunger is located directly over a coarse aggregate particle or a subsurface air void. To account for these possibilities, ASTM C 805 (ASTM, 2002b) requires that ten rebound numbers be taken for a test. If a reading differs by more than six units from the average, that reading should be discarded and a new average should be computed based on the remaining readings. If more than two readings differ from the average by six units, the entire set of readings is discarded.

The rebound hammer was constructed and tested extensively at the Swiss Federal Materials Testing and Experimental Institute in Zurich. A correlation was developed between the compressive strength of standard cubes and the rebound number, and this correlation was provided with the instrument. As other investigators began to develop correlations between strength and rebound number, it became evident that a unique relationship did not exist between strength and rebound number (Kolek, 1958).

FIGURE 21.2 Schematic of ultrasonic pulse velocity method.

The current recommended practice (ACI Committee 228, 2003) is to develop the strength relationship using the same concrete and forming materials as will be used in construction. Without such a correlation, the rebound hammer is useful only for detecting gross changes in concrete quality throughout a structure.

In summary, the rebound number method is recognized as a useful tool for performing quick surveys to assess the uniformity of concrete. Because of the many factors besides concrete strength than can affect rebound number, the author does not recommended this method where reliable strength estimates are needed.

21.2.3 Ultrasonic Pulse Velocity

The ultrasonic pulse velocity method is a stress wave propagation method based on measuring the travel time, over a known path length, of a pulse of ultrasonic compressional waves (stress waves associated with normal stress). The pulses are introduced into the concrete by a piezoelectric transducer, and a similar transducer acts as receiver to monitor the surface vibration caused by the arrival of the pulse. A grease or gel is applied to the faces of the transducers to ensure good coupling with the surfaces. A timing circuit is used to measure the time it takes for the pulse to travel from the transmitter to the receiver. Figure 21.2 provides a schematic of the ultrasonic pulse velocity technique. The speed of compressional waves in a solid is related to the elastic constants (modulus of elasticity and Poisson's ratio) and the density (see Equation 21.15). By conducting tests at various points on a structure, lower quality concrete can be identified by its lower pulse velocity. Naik et al. (2004) provide additional information on the development and application of this method for estimating concrete strength.

The development of a field instrument to measure the pulse velocity occurred nearly simultaneously in Canada and in England (Whitehurst, 1967). These developments were outgrowths of earlier successful work by the U.S. Army Corps of Engineers to measure the speed of a mechanical stress pulse through concrete (Long et al., 1945). The Army Corps of Engineers approach involved attaching two receivers to the concrete surface. A horizontal hammer blow was applied in line with the receivers, and a specially designed electronic interval timer measured the time for the pulse to travel from the first to the second receiver. The major purpose of this technique was to calculate the in-place modulus of elasticity. As will be seen in Section 21.3.3.3, a similar method is still being used to extract information about elastic properties in a layered system.

FIGURE 21.3 Compressive strength vs. pulse velocity relationship based upon 46 mixtures made with the same aggregate. (Adapted from Parker, W.E., *Proc. ASTM*, 53, 1033–1042, 1953.)

In 1946 and 1947, engineers at the Hydro-Electric Power Commission of Ontario (Ontario Hydro) worked on the development of a device to investigate the extent of cracking in dams (Leslie and Cheesman, 1949). The device developed to do so was called the *Soniscope*. It had a 20-kHz transmitting transducer, was capable of penetrating up to 15 m of concrete, and could measure the travel time with an accuracy of 3%. The stated purposes of the *Soniscope* were to identify the presence of internal cracking, determine the depth of surface-opening cracks, and determine the dynamic modulus of concrete (Leslie and Cheesman, 1949). It was further stated that the fundamental measurement was the travel time. The amplitude of the received signal was said to be of secondary importance because the transfer of energy between the transducers and the concrete could not be controlled. It was also emphasized that interpretation of results required knowledge of the history of the structure being investigated.

Early uses of the *Soniscope* on mass concrete emphasized measuring the pulse velocity rather than estimating strength or calculating the modulus of elasticity (Parker, 1953). Based on velocity readings on a grid marked on the surface, the presence of distressed concrete could be easily detected. Parker (1953) reported Ontario Hydro's early attempts to develop relationships between pulse velocity and compressive strength. They investigated 46 mixtures involving the same aggregate, different cement types, and different admixtures. The results indicated no significant differences in the velocity–strength relationships for the different mixtures; therefore, the results were treated as one group, and the best-fit relationship was determined. Figure 21.3 shows the relationship between estimated strength and pulse velocity and the lower 95% confidence limit for estimated strength. Because of the large scatter, the lower confidence limit was about 45% of the mean strength; thus, the inherent uncertainty in using pulse velocity to estimate strength was recognized very early. Figure 21.3 also shows that the change in pulse velocity per unit change in strength decreases with increasing strength. This means that pulse velocity is relatively insensitive to strength for mature concrete.

While work on the *Soniscope* was in progress in Canada, R. Jones and coworkers at the Road Research Laboratory (RRL) in England were involved in independent research to develop an ultrasonic testing apparatus (Jones, 1949a). The RRL researchers were interested in testing the quality of concrete pavements, which involved shorter path lengths compared with the work at Ontario Hydro. As a result, the apparatus that was developed operated at a higher frequency than the *Soniscope*, and it was called the

ultrasonic concrete tester. Transducers with resonant frequencies from 60 to 200 kHz were used, depending on the desired penetration (Jones, 1953). In addition to using a different operating frequency, the RRL device used a different approach than the Soniscope to measure travel time. This was necessary because of the shorter path lengths in the RRL work. It was reported that the ultrasonic concrete tester could measure travel times to within $\pm 2 \mu\text{s}$.

Jones (1949b) reviewed the research carried out with the newly developed ultrasonic concrete tester. Among these studies were the following:

- An investigation into the variations in pulse velocity with height in standard cube specimens and with depth in slabs was one of the first to document the “top-to-bottom” effect that is often mentioned as a problem when planning and interpreting in-place tests (ACI Committee 228, 2003).
- An investigation into the influence of water–cement ratio, aggregate type, and aggregate content on pulse velocity demonstrated the importance of aggregate type and aggregate content on pulse velocity.
- An investigation of the relationships between pulse velocity and compressive strength demonstrated that, for a given mixture under uniform conditions, there was good correlation between strength and pulse velocity.

Thus, Jones revealed the problems inherent in using pulse velocity to estimate concrete strength. Despite these early findings, numerous researchers sought to establish correlations between pulse velocity and strength, and many reached the same conclusions as Jones (Sturrupe et al., 1984).

In the United States, a Soniscope was developed in 1947 at the Portland Cement Association in cooperation with Ontario Hydro, and field applications were reported by Whitehurst (1951). In his summary of the industry’s experience in the United States, Whitehurst published the following tentative classification for using pulse velocity as an indicator of quality:

Pulse Velocity (m/s)	Condition
Above 4570	Excellent
3660–4570	Generally good
3050–3660	Questionable
2130–3050	Generally poor
Below 2130	Very poor

This table was quoted by others in many subsequent publications. Whitehurst warned, however, that these values were established on the basis of tests of normal concrete having a density of about 2400 kg/m^3 and that the boundaries between the conditions could not be sharply drawn. He mentioned that, rather than using these limits, a better approach would be to compare velocities with the velocity in a portion of the structure that is known to be of acceptable quality. Nevertheless, inexperienced investigators often used the above table as the sole basis for interpreting test results.

After the publication of these landmark papers in the late 1940s and early 1950s, a flurry of activity occurred worldwide, and efforts were begun to develop standard test methods. In the United States, a proposed ASTM test method was published in 1955 by Leslie (1955), but it was not until 1967 that it was adopted as a tentative test method (ASTM, 2002a). In Europe, the International Union of Testing and Research Laboratories for Materials and Structures (RILEM) organized a working group to study nondestructive testing (R. Jones was appointed chairman). In 1969, draft recommendations for testing concrete by the ultrasonic pulse method were published (Jones and Făcăoaru, 1969). In Eastern Europe, the method was used extensively as a quality control tool in precast concrete plants.

During the 1960s and 1970s, considerable attention was devoted to gaining more knowledge about the effects of different factors on pulse velocity. Researchers continued to explore the relationship between compressive strength and pulse velocity. They appear, however, to have reached a consensus that there is no unique relationship. Numerous studies showed that the type and quantity of aggregate have major

effects on pulse velocity but not on strength. Significant effort was also devoted to examining whether or not attenuation measurements could provide additional information about concrete strength. These results were, in general, found to be impractical in field situations because of difficulties in achieving consistent coupling of the transducers, which is critical for measuring attenuation.

Perhaps the most significant advances during the 1960s and 1970s were in the development of improved field instrumentation. Due to advances in microelectronic circuitry, the cumbersome instruments developed in the 1940s and 1950s gave way to compact portable devices. In the late 1960s, TNO (Netherlands Organization for Applied Scientific Research) in Delft, Netherlands, developed a portable, battery-operated pulse velocity device that incorporated a digital display of the travel time. In the earlier devices, travel time was measured by examination of oscilloscope displays, which was a time-consuming process. The portable instrument had a resolution of 1 μs , which resulted in low accuracy for short path lengths, and it had limited penetrating ability (Făcăoaru, 1969). At about the same time, R.H. Elvery of University College, London, developed a similar portable device named the *PUNDIT* (Portable Ultrasonic Nondestructive Digital Indicating Tester). It weighed 3.2 kg, had a resolution of 0.5 μs , and could be powered by rechargeable batteries (Malhotra, 1976). These and other relatively low-cost, portable devices simplified testing and resulted in a worldwide increase in the number of consultants and researchers who could perform this type of testing. Later models of these devices had resolutions of 0.1 μs , and some provided an optional output channel to allow the received signal to be displayed on an oscilloscope.

In summary, the ultrasonic pulse velocity test method is a relatively simple test to perform on-site provided it is possible to gain access to both sides of the member. Although tests can be performed with the transducers placed on the same surface, the results are not easy to interpret, and this method of measurement is not recommended. Care must be exercised to ensure that good and consistent coupling with the concrete surfaces is achieved. Other important factors, besides concrete strength, that can affect the measured ultrasonic pulse velocity and that should be considered are discussed in the report of ACI Committee 228 (2003). These factors include:

- Moisture content—An increase in moisture content increases the pulse velocity.
- Presence of reinforcement oriented parallel to the pulse propagation direction—The pulse may propagate through the bars and result in an apparent pulse velocity that is higher than that propagating through concrete.
- Presence of cracks and voids—Cracks and voids can increase the length of the travel path and result in a longer travel time.

Because of these factors, only experienced individuals should use the ultrasonic pulse velocity method for estimating concrete strength. Like the rebound number test, the pulse velocity method is useful for assessing the uniformity of concrete in a structure. It is often used to locate regions in a structure where other tests should be performed or where cores should be drilled.

21.2.4 Probe Penetration

The probe penetration method involves using a gun to drive a hardened steel rod, or probe, into the concrete and measuring the exposed length of the probe. In principle, as the strength of the concrete increases, the exposed probe length also increases; by means of a suitable correlation, the exposed length can be used to estimate compressive strength. Skramtajev mentioned a similar concept in his 1938 summary paper, and Malhotra (1976) noted that similar techniques were reported in 1954. Malhotra and Carette (2004) have provided an in-depth summary of this technique.

Development of the probe penetration test system began in about 1964 as a joint undertaking by T.R. Cantor of the Port of New York Authority and R. Kopf of the Windsor Machinery Company (Arni, 1972). The test system that was eventually commercialized became known as the *Windsor probe*. The apparatus is supplied with a table that relates exposed probe length to compressive strength for various coarse aggregates, which are distinguished by their hardness as measured by the Mohs hardness

FIGURE 21.4 Schematic of conical failure zone during probe penetration test.

scale* of minerals. The basis for the values in the tables and their uncertainty were never published (Arni, 1972). In the late 1960s, independent investigations of the reliability of the Windsor probe system were carried out by the National Ready-Mixed Concrete Association (Gaynor, 1969), the Federal Highway Administration (FHWA) (Arni, 1972), and the Canadian Department of Energy, Mines, and Resources (Malhotra, 1974). In general, it was found that the probe penetration system had acceptable within-test variability. Scatter in the correlation between compressive strength and probe penetration, however, led to high uncertainties in the estimated strength. All investigators cautioned against reliance on the manufacturer's correlation tables.

Arni's (1972) study of the uncertainties of the probe penetration and rebound hammer tests is interesting and worth summarizing. He calculated the number of tests required to detect a strength difference of 1.4 MPa using test cylinders, probe penetration, or rebound number. These estimates were based on the variability of test results and slopes of the correlation equations developed in the FHWA study. For 90% confidence levels, the results were as follows:

Test Method	Number of Tests
Cylinders	8
Rebound number	120
Probe penetration	85

Note that these numbers apply for specific data used by Arni. Nevertheless, they point out the inherent inability of in-place tests to detect small differences in concrete strength unless large numbers of tests are performed. This important concept has been largely ignored.

The probe penetration test method was adopted as a tentative ASTM standard (C 803) in 1975. In 1990, the standard was modified to include the use of a pin penetration device, in which a small pin is forced into the concrete using a spring-loaded driver (ACI Committee 228, 2003; Malhotra and Carrette, 2004; Nasser and Al-Manseer, 1987a,b).

The report of ACI Committee 228 (2003) provides an explanation of the factors affecting probe penetration into concrete. Figure 21.4 is a schematic of the failure zone produced during probe penetration. The probe penetrates until its initial kinetic energy is absorbed by friction and the fracture of the mortar and aggregate. Hence, the strength properties of the aggregate affect the penetration depth. As a result, the strength relationship depends on the aggregate type. For equal concrete strength, probe penetration would be deeper in a concrete with a soft aggregate than in a concrete with a hard aggregate. See Malhotra (1976), Bungey and Millard (1996), and Malhotra and Carrette (2004) for additional information on the effects of

* A qualitative scale in which the hardness of a mineral is determined by its ability to scratch, or be scratched by, another mineral. The hardest mineral is diamond and the softest is talc.

FIGURE 21.5 Schematic of cast-in-place pullout test.

aggregate type. Probe penetration is not strongly affected by the near-surface conditions and is therefore not as sensitive to surface conditions as the rebound number method. The direction of penetration is not important provided that the probe is fired perpendicular to the surface. Care must be exercised when testing reinforced concrete to ensure that tests are not carried out in the vicinity of the reinforcing steel, especially if the concrete cover is low. In practice, probe penetration tests should not be used to investigate low standard cylinder test results unless a correlation is developed for the specific concrete mixture.

21.2.5 Pullout Test

The cast-in-place pullout test is one of the most reliable techniques for estimating the in-place strength of concrete during construction. In this method, an insert with an enlarged head is cast in the concrete. The insert and the accompanying conical fragment of concrete are extracted by using a tension-loading device reacting against a bearing ring that is concentric with the insert (Figure 21.5). The force required to pull out the insert is an indicator of concrete strength. A comprehensive review of the history and theory of the pullout test is available (Carino, 2004b), and only a brief summary is provided here.

21.2.5.1 History

Ideas for pullout tests apparently originated in the Soviet Union (Skramtajev, 1938). Tremper (1944) was the first American to report on the correlation between pullout force and companion cylinder strength. The insert developed by Volf (of the Soviet Union) and the one used by Tremper are shown in Figure 21.6a and Figure 21.6b, respectively. In both cases, the reaction to the pullout force was applied sufficiently far from the insert that there was negligible interaction between the failure surface and the reaction system. As a result, failure was controlled primarily by the tensile strength of the concrete. This explains why Tremper found that the correlation between pullout force and compressive strength was nonlinear.

Despite Tremper's encouraging results, no additional documented work on the pullout test was carried out until 1962, when a comprehensive study was begun in Denmark (Kierkegaard-Hansen, 1975). The objective was to find the optimum geometry for a field test system that would have a high correlation between pullout load and the compressive strength of concrete. Kierkegaard-Hansen found that the correlation could be improved by constraining the failure surface to follow a predefined path by using a relatively small-diameter reaction ring. The study resulted in the pullout test configuration shown in Figure 21.6c, which was eventually incorporated into the Lok-Test[®] system, which is the most widely used commercial pullout test system.

* As explained by Kierkegaard-Hansen (1975), failure when a small reaction ring is used can be considered a punching type of failure. The Danish word for "punching" is *lokning*, so the term *lok-strength* was used to describe the strength measured by the test.

FIGURE 21.6 Various pullout test configurations.

Owen Richards, a materials consultant in the United States, carried out independent studies of a pullout test in the late 1960s and early 1970s (Richards, 1977). The early version of Richards' pullout test configuration was larger than that developed in Denmark. The inserts were manufactured from 19-mm threaded rods, and washers were used to provide the enlarged head. Nuts were used to add rigidity to the washers and to fix the embedment depth of the washers. The test geometry, which is shown in Figure 21.6d, resulted in an idealized failure surface with an area approximately equal to the area of a standard 152-mm-diameter cylinder. Richards preferred to divide the pullout force by the nominal area of the idealized failure to obtain pullout strength, which is a fictitious quantity because the pullout force is inclined to the surface area.

The first reported pullout tests using Richards' early system were performed at the Bureau of Reclamation (Rutenbeck, 1973). Strong correlation was obtained between pullout tests performed on slabs and the compressive strength of companion cylinders. Good correlation between pullout strength and compressive strength was also obtained when the inserts were placed in shotcrete panels and compressive strength test specimens were cut from the panels. In 1975, Malhotra also reported on the applicability of Richards' pullout test (Malhotra, 1975). It was found that the coefficient of variation for three replicate tests was less than 5%, which was very encouraging. In a later study (Malhotra and Carette, 1980), it was noted that similar correlations were obtained in different investigations of Richards' system.

Richards' pullout system produced encouraging results, but the large size of the insert required heavy testing equipment and produced significant surface damage. In 1977, a smaller version of the test system was introduced (Richards, 1977), as shown in Figure 21.6e. The apex angle of the conic frustum was maintained at 67° , but the insert was constructed from one piece of steel. The enlarged end of the shank accommodated a pull-rod that passed through a center-hole tension ram. In the early 1960s, investigations of the pullout test were also conducted in Great Britain (Te'eni, 1970), but the work was apparently never carried to the stage of a practical field test system. A novel feature of the British work was the use of a power function for the correlation equation, rather than a straight line as had been used in Denmark, the United States, and Canada. The usefulness of the pullout test for estimating early-age strength was quickly recognized. In 1978, ASTM adopted a tentative test method for the pullout test (ASTM C 900; see ASTM, 2006c). In North America, J. Bickley became an early advocate of the pullout test method as a tool for accelerating construction schedules without compromising safety (Bickley, 1982a).

21.2.5.2 Failure Mechanism

Ever since the pullout test was first described by Skramtajev (1938), its failure mechanism has not been completely understood. Skramtajev correctly noted that the test subjects the concrete to a combination of tensile and shearing stresses. Kierkegaard-Hansen (1975), the inventor of the widely used Lok-Test system, tried to relate the shape of the extracted conical fragment to the intact cones often observed at the ends of cylinders tested in compression. Jensen and Braestrup (1976) used plasticity theory to relate the ultimate pullout force to the compressive strength of the concrete. Malhotra and Carette (1980) proposed that the pullout strength was related to the direct shear strength of concrete. In the 1980s and 1990s, experimental and analytical studies tried to gain a better understanding of the failure process during the pullout test (Ballarini et al., 1986; Hellier et al., 1987; Krenchel and Bickley, 1987; Krenchel and Shah, 1985; Ottosen, 1981; Stone and Carino, 1983; Yener, 1994). From these independent analytical and experimental studies, it is now understood that the pullout test subjects the concrete to a nonuniform, three-dimensional state of stress. It also has been demonstrated that the failure process involves two circumferential crack systems: (1) a stable system that starts at the insert head at about one third of the ultimate load, propagates into the concrete at a large apex angle, and is arrested as it reaches a tension-free region; and (2) a system that propagates with increasing load and eventually defines the shape of the extracted cone. Figure 21.7 shows these cracking systems as predicted by Hellier et al. (1987), who used a discrete cracking, finite-element model based on nonlinear fracture mechanics.

Despite general agreement on the cracking process prior to the attainment of ultimate pullout load, no consensus has been reached on the failure mechanism at the ultimate load. Some researchers maintain that ultimate load occurs as a result of compressive failure along a strut running from the bottom of the bearing ring to the insert head (Krenchel and Bickley, 1987; Krenchel and Shah, 1985; Ottosen, 1981). This mechanism has been used to explain the good correlation between pullout strength and compressive strength. Others maintain that ultimate failure is governed by aggregate interlock across the secondary crack system, and the ultimate load is reached when sufficient aggregate particles have been pulled out of the mortar matrix (Hellier et al., 1987; Stone and Carino, 1983). In this case, it is argued that there is correlation between pullout strength and compressive strength because both properties are controlled by the tensile strength of the mortar. In the compression test, the ultimate load is associated with the formation and growth of microcracks through the mortar.

Although there is no agreement on the exact failure mechanism of the pullout test, it has been shown that the pullout strength has strong correlation with the compressive strength of concrete and that the test has good repeatability. In a review of published data, ACI Committee 228 (2003) recommended a coefficient of variation (standard deviation divided by the mean) of 8% for the pullout test. The current version of ASTM C 900 (ASTM, 2006) requires at least five individual pullout tests for each 115 m^3 of concrete in a given placement. For tests of the same concrete, the precision statement of ASTM C 900 states that the acceptable range of five replicate tests is 31% of the average. If the range should exceed this value in the field, a closer examination is required to understand the underlying reason for the greater than expected scatter.

FIGURE 21.7 Crack systems formed during pullout test based on fracture analysis using the finite-element method. (From Hellier, A.K. et al., *J. Cement Concrete Aggregates*, 9(1),20–29, 1987.)

21.2.5.3 Post-Installed Tests

A drawback of the cast-in-place (CIP) pullout test is that the locations of the inserts have to be planned in advance of concrete placement, and the inserts must be fastened to the formwork. This limits the applicability of the CIP method to new construction. In an effort to extend the application of pullout testing to existing structures, various techniques for performing post-installed pullout tests have been investigated. Some of these approaches are shown in Figure 21.8.

During the 1970s, a need arose in the United Kingdom for in-place tests to evaluate distressed concrete structures built with high-alumina cement. Researchers at the Building Research Establishment (BRE) developed a pullout technique using commercial anchor bolts, as shown in Figure 21.8a (Chabowski and Bryden-Smith, 1980). A 6-mm-diameter hole is drilled into the concrete, and an anchor bolt is inserted so the split-sleeve is at a depth of 20 mm. After applying an initial load to expand and engage the sleeve, the bolt is pulled out, and the maximum load during the extraction is recorded. Because of the shallow embedment, failure occurs by concrete fracture. Reaction to the pullout load is provided by three reaction points located along the perimeter of a 80-mm-diameter ring. As the bolt is pulled, the sleeve imparts longitudinal and transverse forces to the concrete. Hence, the fracture surface differs from that in the cast-in-place pullout test, and the test has been referred to as an *internal fracture test* rather than a pullout test. The correlation between ultimate load and compressive strength was found to have a pronounced nonlinearity, indicating that the failure mechanism was probably related to the tensile strength of the concrete. Within-test variability was found to be greater than the CIP pullout test, and the 95% confidence limits of the correlation relationship were found to range between $\pm 30\%$ of the mean curve (Chabowski and Bryden-Smith, 1980). The relatively low precision of the internal fracture test has been attributed to two principal causes (Bungey and Millard, 1996): (1) variability in the hole drilling and test preparation, and (2) the influence of aggregate particles on the load-transfer mechanism and the failure-initiation load.

Mailhot et al. (1979) also investigated the feasibility of several post-installed pullout tests. One of these used a split-sleeve and a tapered bolt assembly that was placed in a 19-mm-diameter hole drilled into the concrete. As shown in Figure 21.8b, the details differ from the BRE method because the reaction to the pulling force acts through a specially designed high-strength, split-sleeve assembly. The force transmitted to the concrete is predominantly in the lateral direction because the tapered bolt forces the sleeve to expand laterally. It is likely that failure occurs by indirect tensile splitting, similar to that in a standard

(a) BRE Internal Fracture Test

(b) Expanding Sleeve Test

(c) CAPO Test

FIGURE 21.8 Examples of post-installed pullout tests.

splitting-tension test. As with the BRE test, the variability of this test was reported to be rather high. Another successful method involved epoxy grouting a 16-mm-diameter threaded rod into a 19-mm hole to a depth of 38 mm. After the epoxy had cured, the rod was pulled using a tension jack reacting against a bearing ring. This method was also reported to have high variability. The study concluded that these

two methods had the potential for assessing the strength in existing construction. Additional research was recommended, however, to enhance their reliability.

Domone and Castro (1986) also developed a technique similar to the expanding sleeve method shown in Figure 21.8b; however, a torque meter was used to apply the load, and the embedment was 20 mm, as in the BRE method. On the basis of a limited number of tests, it was concluded that this method gave better correlations than the BRE method.

Another method developed by the manufacturer of the Lok-Test^{*} system is referred to as the **CAPO** (Cut and Pullout) test (Petersen, 1984). The method involves drilling an 18-mm-diameter hole into the concrete and using a special milling tool to undercut a 25-mm-diameter slot at a depth of 25 mm. An expandable ring is placed in the hole, and the ring is expanded using special hardware. Figure 21.8c shows the ring after expansion. The entire assembly used to expand the ring is pulled out of the concrete using the same loading system as for a CIP pullout test. Unlike the methods discussed above, the CAPO test subjects the concrete to a similar state of stress as the CIP pullout test. The performance of the CAPO test in laboratory evaluations has been reported to be similar to that for the Lok-Test (Petersen, 1984). Early users of the CAPO test noted that the test was cumbersome to perform and care must be taken to control the variability (Read et al., 1991). The current apparatus has been refined to make it easier to prepare a test surface that is flat and perpendicular to the drilled hole. In 1999, ASTM C 900 was revised to include post-installed pullout tests based on the CAPO procedure. The ASTM procedures require that care be exercised to ensure properly aligned hardware and a properly seated reaction ring. Criteria are provided for acceptable failure geometries when the conic frustum is extracted.

21.2.6 Break-Off Test

This test measures the force required to break off a cylindrical core from the concrete mass. The method was developed in the early 1970s by R. Johansen at the Cement and Concrete Research Institute in Norway. In cooperation with contractors, Johansen sought a simple, inexpensive, and robust method to measure in-place strength (Johansen, 1977, 1979). The test method was standardized by ASTM in 1990 (ASTM C 1150; see ASTM, 1996). Naik et al. (2004) have provided a comprehensive review of research results.

Figure 21.9 provides a schematic of the break-off test. For new construction, the core is formed by inserting a special plastic mold into the fresh concrete. The mold results in a core specimen with a recessed annular void at the surface. When the in-place strength is to be estimated, the mold is removed, and a special, hand-operated, hydraulic loading jack is placed into the annular space. The jack applies a force to the top of the core until it ruptures from the concrete mass. The hydraulic fluid pressure in the jack is monitored with a pressure gauge, and the maximum pressure gauge reading in units of bar (1 bar = 0.1 MPa) is referred to as the *break-off number* of the concrete. For new construction, the molds are inserted into the top surface of the member after the concrete has been leveled. Alternatively, the molds can be attached to the sides of the formwork and filled during concrete placement. For existing construction, a special drill bit can be used to cut the core and the annular space to accept the loading the system.

For ease of mold insertion into the fresh concrete, the concrete must be workable. In addition, to minimize interference, the maximum aggregate size should be limited to a fraction of the mold diameter, which is 55 mm. The break-off test is not recommended for concrete having a maximum nominal aggregate size greater than 25 mm. Mold insertion must be performed carefully to ensure good compaction around the mold and a minimum of disturbance at the base of the formed core. Some problems have been reported with keeping the molds from floating out of very fluid concrete mixtures (Naik et al., 1987).

The break-off test subjects the concrete to a slowly applied force and measures a static strength property of the concrete. The core is loaded as a cantilever, and the concrete at the base of the core is subjected to a combination of bending and shearing stresses. In early work (Johansen, 1977, 1979), break-off

^{*} Certain trade names and company products are mentioned to identify specific test equipment. In no case does such identification imply recommendation or endorsement by the author, nor does it imply that the products are necessarily the best available for the purpose.

FIGURE 21.9 Schematic of break-off test.

strength was reported as the calculated flexural stress at the base of the core corresponding to the rupture force. In later applications (see review by Naik, 2004), the flexural strength was not computed, and the break-off number (pressure gauge reading) was related directly to compressive strength. This approach simplifies data analysis. Calibration of the test instrument is critical to ensure that gauge readings correspond to actual forces applied to the test specimen.

The correlations between break-off strength and compressive strength have been found to be nonlinear (Barker and Ramirez, 1988; Johansen, 1977, 1979), which is in accordance with the usual practice of relating the modulus of rupture of concrete to the square root of compressive strength. It has also been found that the correlation between break-off strength and modulus of rupture may be more uncertain than that between break-off strength and compressive strength (Barker and Ramirez, 1988).

Failure during the break-off test occurs by fracture at the base of the 55-mm-diameter core. The crack initiates at the most highly stressed point. It then propagates through the mortar and, in most cases, around coarse aggregate particles located at the base of the core. The particular arrangement of aggregate particles within the failure region would be expected to affect the ultimate load in each test. Because of the relatively small size of the core and the heterogeneous nature of concrete, the distribution of aggregate particles will be different at each test location. Hence, one would expect the within-test variability of the break-off test to be higher than that of other standard strength tests that involve larger test specimens. One would also expect that the variability might be affected by maximum aggregate size and aggregate shape. The developer of the break-off test reported a within-test coefficient of variation of about 9% (Johansen, 1979). This value has, in general, been confirmed by other investigators (Carino, 1992a).

In 2002, ASTM Committee C09 voted to withdraw ASTM C 1150. The break-off test was not being used in practice and testing equipment was no longer available commercially. This is unfortunate because the author feels that the break-off test could have become a good method for estimating in-place strength in existing structures.

21.2.7 Maturity Method

The maturity method is a technique for estimating the early strength development of concrete during its curing period by measuring the temperature history of the concrete. Carino (2004a) provides a comprehensive review of the history of the method and some of its applications. Historically, the maturity method was not classified as a nondestructive test method, but it is now regarded as a useful technique for estimating in-place strength. Its origin can be traced to a series of papers from England dealing with

accelerated steam curing methods (McIntosh, 1949; Nurse, 1949; Saul, 1951). There was a need for a procedure to account for the combined effects of time and temperature on strength development for different elevated-temperature curing processes. It was proposed that the product of time and temperature could be used for this purpose. These ideas led to the famous **Nurse–Saul maturity function**:

$$M = \sum_0^t (T - T_0) \Delta t \quad (21.1)$$

where:

M = maturity index, degree Celsius-hour (or degree Celsius-day).

T = average concrete temperature (degree Celsius) during the time interval Δt .

T_0 = datum temperature (usually taken to be 10°C).

Δt = time interval (hour or day).

The index computed by Equation 21.1 was referred to as the *maturity*; however, the current terminology is the *temperature–time factor* (ASTM C 1074; see ASTM, 2004a). Saul (1951) presented the following principle, which has become known as the **maturity rule**:

Concrete of the same mix at the same maturity (reckoned in temperature–time) has approximately the same strength whatever combination of temperature and time go to make up that maturity.

Equation 21.1 is based on the assumption that the initial rate of strength gain (during the acceleratory period following setting) is a linear function of temperature. It was soon realized, however, that this approximation may not be valid when curing temperatures vary over a wide range. As a result, a series of alternatives to the Nurse–Saul function were proposed by other researchers (Malhotra, 1971). None of the alternatives, however, received widespread acceptance, and the Nurse–Saul function was used worldwide until an improved function was proposed in the 1970s.

In 1977, a new function was proposed to compute a maturity index from the recorded temperature history of the concrete (Freiesleben Hansen and Pedersen, 1977). This function was based on the Arrhenius equation (Brown and LeMay, 1988), which is used to describe the effect of temperature on the initial rate of a chemical reaction. The new function allowed the computation of the equivalent age of concrete at a reference temperature as follows:

$$t_e = \sum_0^t e^{\frac{-E}{R} \left(\frac{1}{T} - \frac{1}{T_r} \right)} \Delta t \quad (21.2)$$

where:

t_e = equivalent age at the reference temperature (hour or day).

E = apparent activation energy (J/mol).

R = universal gas constant = 8.314 J/mol-K.

T = average absolute temperature of the concrete during interval Δt (degrees Kelvin).

T_r = absolute reference temperature (degrees Kelvin).

By using Equation 21.2, the actual age of the concrete is converted to its equivalent age, in terms of strength gain, at the reference temperature. In European practice, the reference temperature is usually taken to be 20°C, whereas in North American practice it is usually taken to be 23°C. The introduction of this function overcame one of the main limitations of the Nurse–Saul function (Equation 21.1) because it allowed for a nonlinear relationship between the initial rate of strength development and curing temperature. This temperature dependence is described by the value of the apparent activation energy. Comparative studies in the early 1980s showed that this new maturity function was superior to the Nurse–Saul function (Byfors, 1980; Carino, 1982).

21.2.7.1 Effect of Temperature on Strength Gain

The key parameter in Equation 21.2 is the “activation energy,” which describes the effect of temperature on the initial rate of strength development. In the early 1980s, the author began a series of studies to gain a better understanding of the maturity method (Carino, 1984). From this work, a procedure was developed to obtain the activation energy of a given cementitious mixture. The procedure is based on determining the effect of curing temperature on the rate constant for strength development. The rate constant is related to the curing time required to reach a certain fraction of the long-term strength, and it is obtained by fitting an appropriate equation to the strength-vs.-age data acquired under constant temperature (isothermal) curing. The procedure to determine the activation energy consists of the following steps:

- Cure mortar specimens at different constant temperatures.
- Determine compressive strengths at regularly spaced ages.
- Determine the value of the rate constant at each temperature by fitting a strength–age relationship to each set of strength–age data.
- Determine the best-fit Arrhenius equation (to be explained) to represent the variation of the rate constant with the temperature.

By using the above procedure, the activation energy was determined for concrete and mortar specimens made with different cementitious materials (Carino and Tank, 1992; Tank and Carino, 1991). It was found that for concrete with a water–cement ratio (w/c) of 0.45, the activation energy ranged from 30 to 64 kJ/mol; for a w/c of 0.60, it ranged from 31 to 56 kJ/mol, depending on the type of cementitious materials and admixtures.

The significance of the activation energy is explained further here. In Equation 21.2, the exponential term within the summation sign converts increments of actual curing time at the concrete temperature to equivalent increments at the reference temperature. Thus, the exponential term can be considered as an **age conversion factor** (γ):

$$\gamma = e^{\frac{-E}{R} \left(\frac{1}{T} - \frac{1}{T_r} \right)} \quad (21.3)$$

Figure 21.10 shows how the age conversion factor varies with curing temperature for different values of the activation energy. The reference temperature is taken as 23°C. It is seen that for an activation energy of 30 kJ/mol, the age conversion factor is nearly a linear function of temperature. In this case, the Nurse–Saul equation would be a reasonably accurate maturity function to account for the combined effects of time and temperature, because the Nurse–Saul function assumes that the rate constant varies linearly with temperature (Carino, 1984). For an activation energy of 60 kJ/mol, the age conversion factor is a highly nonlinear function of the curing temperature. In this case, the Nurse–Saul function would be an inaccurate maturity function if the temperature were to vary over a wide range. In summary, Figure 21.10 shows the nature of the error in an age conversion factor if the incorrect value of activation energy were used for a particular concrete mixture. The magnitude of the error in the computed maturity index would increase with increasing difference of the curing temperature from the reference temperature.

The reader will have noticed that the term *activation energy* was introduced with quotation marks. This is because the E -value that is determined when the rate constant is plotted as a function of the curing temperature is not truly the activation energy as implied by the Arrhenius equation. The following discussion is provided for those unfamiliar with the concept of activation energy or the origin of the Arrhenius equation.

The idea of activation energy was proposed by Svante Arrhenius in 1888 to explain why chemical reactions do not occur instantaneously when reactants are brought together, even though the reaction products are at a lower energy state (Brown and LeMay, 1988). Arrhenius proposed that, before the lower energy state is achieved, the reactants must have sufficient energy to overcome an energy barrier that separates the unreacted state from the reacted state. A physical analogy is a brick standing upright. The

FIGURE 21.10 Effect of activation energy value on the age conversion factor.

brick will not instantaneously tip over to its lower energy state, which is the brick lying in a horizontal position. It must be pushed from the higher to the lower energy state. The energy required to push the brick from its upright position to the point of instability, after which the brick falls on its own, is the activation energy for this process.

For molecular systems, the reactant molecules are in constant motion and energy is transferred between them as they collide (Brown and LeMay, 1988). A certain number of molecules will acquire sufficient energy in these collisions to surmount the energy barrier and form the lower energy reaction product. As the system is heated, the kinetic energy of the molecules increases and more molecules will surmount the barrier; thus, the rate of reaction increases with increasing temperature. Arrhenius observed that the rate constant k of many reactions increased with temperature according to an exponential function, which has since been called the *Arrhenius equation*, as follows:

$$k = Ae^{\frac{-E}{RT}} \quad (21.4)$$

The term A is the frequency factor and is related to the frequency of collisions and the probability that the molecules will be favorably oriented for reaction (Brown and LeMay, 1988). It can be seen that the age conversion factor given by Equation 21.2 is simply the ratio of the rate constants at two different temperatures:

$$\gamma = \frac{k}{k_r} = \frac{e^{\frac{-E}{RT}}}{e^{\frac{-E}{RT_r}}} = e^{\frac{-E}{R} \left(\frac{1}{T} - \frac{1}{T_r} \right)} \quad (21.5)$$

The Arrhenius equation was derived empirically from observations of homogeneous chemical systems undergoing a single reaction. Roy and Idorn (1982) noted that researchers "... have cautioned that since cement is a multiphase material and also the process of cement hydration is not a simple reaction, homogeneous reaction kinetics cannot be applied." Thus, the activation energy obtained from strength-gain data or degree of hydration data is not a true activation energy as originally proposed by Arrhenius.

The author believes that the Arrhenius equation happens to be one of several equations that can be used to describe the nonlinear variation of the rate constant for strength gain (or degree of hydration) with curing temperature. This has been the motivation for proposing a simpler exponential function than Equation 21.2 to compute equivalent age (Carino, 1982; Carino and Tank, 1992; Tank and Carino, 1991). It has been suggested that the temperature dependence of the rate constant for strength gain can be represented by the following:

$$k = A_0 e^{BT} \quad (21.6)$$

where:

- A_0 = value of the rate constant at 0°C.
- B = temperature sensitivity factor (1/°C).
- T = concrete temperature (°C).

Based on Equation 21.6, the equation for equivalent age at the reference temperature T_r is as follows:

$$t_e = \sum_0^t e^{B(T-T_r)} \Delta t \quad (21.7)$$

where:

- B = temperature sensitivity factor (1/°C).
- T = average concrete temperature during time interval Δt (°C).
- T_r = reference temperature (°C).

It has been shown that Equation 21.2 and Equation 21.7 would result in similar values of equivalent age (Carino, 1992a) for a given temperature history. The author believes Equation 21.7 has the following advantages over Equation 21.2:

- The temperature sensitivity factor (B) has more physical significance compared with the apparent activation energy; for each temperature increment of $1/B$, the rate constant for strength development increases by a factor of approximately 2.7.
- Temperatures do not have to be converted to the absolute scale.
- Equation 21.7 is a simpler equation.

21.2.7.2 Strength Development Relationships

The key to developing an accurate maturity function for a particular concrete mixture is to determine the variation of the rate constant with curing temperature. Strictly speaking, a rate constant represents the rate at which a chemical reaction occurs at a given temperature. In the context of this discussion, however, the rate constant is related to the initial rate of strength gain at a constant temperature, and it can be obtained from the equation of strength vs. age. Thus, it is necessary to consider some of the relationships that have been used to represent the isothermal strength development of concrete. The author has successfully used the following hyperbolic equation to represent strength gain at constant curing temperature up to equivalent ages at 23°C of about 28 days:

$$S = S_u \frac{k(t-t_0)}{1+k(t-t_0)} \quad (21.8)$$

where:

- S = strength at age t (MPa).
- t = age of concrete (days).
- S_u = "limiting" strength.
- k = rate constant (1/day).
- t_0 = age at start of strength development (days).

The basis of this equation has been explained elsewhere (Carino, 1984; Knudsen, 1980). This equation assumes that strength development begins instantaneously at age t_0 ; thus, the gradual strength development during the setting period is not considered. The parameters S_u , k , and t_0 are obtained by least-squares curve fitting to the strength-vs.-age data. The limiting strength (S_u) is the asymptotic value of the strength for the hyperbolic function that fits the data. As will be discussed, the best-fit value for S_u does not necessarily represent the actual long-term strength of the concrete, and that is why the quotation marks were used in the definition following Equation 21.8. For the hyperbolic equation, the rate constant has the following property: When the age beyond t_0 is equal to $1/k$, the strength equals 50% of the limiting strength, or $0.5(S_u)$.

An equation similar to Equation 21.8 was also used by Knudsen (1980) and Geiker (1983) to represent the degree of hydration and development of chemical shrinkage as a function of age. Geiker (1983) noted, however, that Equation 21.8 gave a poor fit for certain cementitious systems. It was found that the following version of the hyperbolic equation gave a better fit to certain data than Equation 21.8 (Knudsen, 1984):

$$S = S_u \frac{\sqrt{k(t-t_0)}}{1 + \sqrt{k(t-t_0)}} \quad (21.9)$$

Knudsen explained the differences between Equation 21.8 and Equation 21.9 in terms of the hydration kinetics of individual cement particles. Equation 21.8 is based on **linear kinetics**, which means that the degree of hydration of an individual cement particle is a linear function of the product of time and the rate constant. Equation 21.9 is based on **parabolic kinetics**, which means that the degree of hydration is a function of the square root of the product of time and the rate constant. Thus, Equation 21.8 and Equation 21.9 are called the *linear hyperbolic model* and *parabolic hyperbolic model*, respectively.

Freiesleben Hansen and Pedersen (1985) proposed the following exponential equation to represent the strength development of concrete:

$$S = S_u e^{-\left(\frac{\tau}{t}\right)^\alpha} \quad (21.10)$$

where:

τ = a time constant.

α = a shape parameter.

This equation can model the gradual strength development occurring during the setting period, and it is also asymptotic to a limiting strength. The time constant τ represents the age at which the strength has reached $0.37(S_u)$; thus, the value of $1/\tau$ can be considered as the rate constant for this equation. The shape parameter α affects the slope of the curve during the acceleratory period (following the induction period*), and it affects the rate at which the strength approaches the limiting strength.

Figure 21.11 illustrates the performance of these equations in representing actual strength development data. Figure 21.11a shows strength data for mortar cubes cured at room temperature and tested at ages from 0.4 to 56 days. Figure 21.11b shows data for standard-cured concrete cylinders tested at ages from 7 days to 3.5 years (Carette and Malhotra, 1991). The curves are the best-fit curves for Equation 21.8, Equation 21.9, and Equation 21.10. For the mortar data, the linear hyperbolic function and the exponential function fit the data well, and these curves are nearly indistinguishable in Figure 21.11a. For the longer term concrete data, the parabolic hyperbolic function and the exponential function fit the data better than the linear hyperbolic function, and the curves based on these two functions cannot be distinguished in Figure 21.11b.

* After cement and water are mixed together, there is a time delay before strength development begins. This period is referred to as the *induction period*. After the induction period, strength development is rapid, and this is known as the *acceleratory period*.

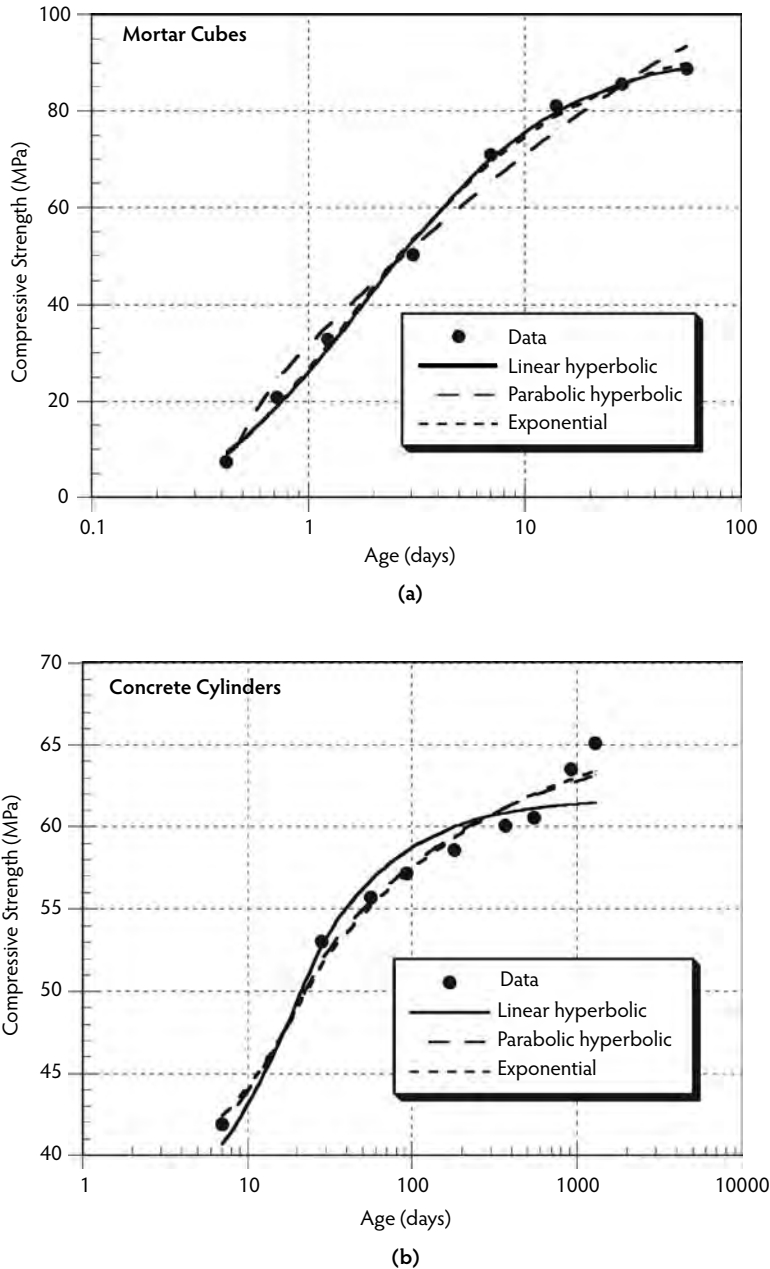

FIGURE 21.11 Fit of strength–age models to experimental data: (a) mortar cubes, and (b) concrete cylinders.

The results shown in Figure 21.11 highlight the capabilities of the various strength–age functions. The linear hyperbolic function appears to be a good model for strength development up to about 28 days (equivalent age) but not for later ages. The parabolic hyperbolic function appears to be better suited for modeling later age strength gain. The exponential model appears to be capable of modeling strength gain over the full spectrum of ages.

The inherent limitation of the linear hyperbolic function can be understood by considering the ratio of the limiting strength to the 28-day strength. If the t_0 term in Equation 21.8 is neglected, the following equation is obtained for this ratio:

$$\frac{S_u}{S_{28}} = \beta = 1 + \frac{1}{28k} \quad (21.11)$$

Thus, the value of β (the ratio of limiting strength to 28-day strength) is directly related to the rate constant. A higher value of k results in a lower value of β , which means a smaller difference between the limiting strength and the 28-day strength. The rate constant, in turn, is controlled primarily by the initial rate of strength development. The fact is that the ratio of the actual long-term strength of concrete to the 28-day strength does not obey Equation 21.11. This means that values of S_u obtained by fitting the linear hyperbolic model to strength–age data will be lower than the actual long-term strength of concrete if it is allowed to cure for a long time.

On the basis of the above discussion, one might conclude that the exponential model given by Equation 21.10 is the best model to use for determining the rate constant at a particular curing temperature. This would be correct if shape parameter α were independent of the curing temperature; however, test results show that this is not always the case (Carino et al., 1992). Thus, a maturity function based solely on the variation of the rate constant ($1/\tau$) with temperature would not be able to account accurately for the combined effects of time and temperature on strength development.

Which strength-gain function should be used? The maturity method is typically used to monitor strength development during construction; therefore, it is not necessary to accurately model the strength gain at later ages. Thus, the author believes that the linear hyperbolic function can be used to analyze strength data, up to an equivalent age of 28 days, to determine the variation of the rate constant with curing temperature. Knudsen (1985) suggested that the linear hyperbolic function is suitable up to a degree of hydration of 85%. The suitability of the linear hyperbolic function was also demonstrated in a study on the applicability of the maturity method to mortar mixtures with low ratios of water to cementitious materials, typical of those in high-performance concrete (Carino et al., 1992).

21.2.7.3 Estimating Strength

The final discussion deals with estimating strength by the maturity method. The maturity method is generally used to estimate the in-place strength of concrete by using the in-place maturity index and a previously established relationship between maturity index and strength. This assumes that a given concrete possesses a unique relationship between strength and the maturity index. This assumption would be acceptable if the long-term strength of concrete were independent of the curing temperature, but this is not the case. It is known that the long-term strength is affected by the initial temperature of the concrete. Thus, if the same concrete mixture were used for a cold-weather placement and a hot-weather placement, the strength would not be the same for a given maturity index. It has been proposed that the correct application of the maturity method is to estimate **relative strength**. Tank and Carino (1991) proposed the following **rate constant model** of relative strength development in terms of equivalent age:

$$\frac{S}{S_u} = \frac{k_r(t_e - t_{0r})}{1 + k_r(t - t_{0r})} \quad (21.12)$$

where:

k_r = value of the rate constant at the reference temperature.

t_{0r} = age at start of strength development at the reference temperature.

The previous discussion has shown that, for the linear hyperbolic function, the ratio S/S_u may not indicate the true fraction of the long-term strength because the calculated value of S_u may not be the actual long-term strength. This deficiency can be overcome by expressing relative strength as a fraction of the strength at an equivalent age of 28 days. By using the definition of β in Equation 21.11, the relative strength gain equation would be as follows:

$$\frac{S}{S_{28}} = \beta \frac{k_r(t_e - t_{0r})}{1 + k_r(t - t_{0r})} \quad (21.13)$$

The value of β would be obtained by fitting Equation 21.8 to data of strength vs. equivalent age. Then, the value of S_u is divided by the estimated strength, from the best-fit curve, at an equivalent age of 28 days.

To summarize, the following points represent the author's ideas about the maturity method:

- No single maturity function is applicable to all concrete mixtures. The applicable maturity function for a given concrete can be obtained by determining the variation of the rate constant with the curing temperature.
- The linear hyperbolic function can be used to analyze strength–age data to obtain the rate constants at different curing temperatures.
- Equation 21.6 can be used to represent the variation of the rate constant with curing temperature. The temperature-sensitivity factor governs the rate at which the rate constant increases with temperature and is analogous to the activation energy in the Arrhenius equation.
- The equivalent age can be calculated from the temperature history using Equation 21.7.
- The maturity method is more reliable for estimating relative strength development than for estimating absolute strength.

21.2.7.4 Maturity and Other Properties

The development of mechanical and transport properties of concrete is related to the degree of hydration of the cementitious materials; thus, it would be expected that the early development of other properties besides compressive strength could be related to a maturity index. Lew and Reichard (1978) showed that the development of modulus of elasticity, splitting tensile strength, and pullout bond strength could be related to the temperature–time factor. More recently, Dellate et al. (2000) related the development of splitting tensile strength and tensile bond strength of concrete overlays to the temperature–time factor. Yu and Ansari (1996) studied the development of fracture energy under different curing temperatures and found that the activation energy for development of fracture toughness was the same as for development of compressive strength. The values of fracture energy measured under different curing temperatures fell on the same curve when plotted as a function of equivalent age. Dilly and Zollinger (1998) also related the development of fracture strength to equivalent age. Pinto et al. (2001) found that the development of compressional wave speed under different curing temperatures could be related to equivalent age.

Pinto and Hover (1999) investigated whether the maturity method was applicable to the setting time of concrete measured in accordance with ASTM C 403/C 403M (see ASTM, 2006d). They found that the setting time at different temperatures could be used to obtain an apparent activation energy to represent the temperature dependence of setting time. The inverses of the setting times were used as rate constants, and the natural logarithms of the rate constants were plotted as a function of the inverse of absolute temperature. They found that the activation energy based on setting time was similar to the value recommended in ASTM C 1074 (ASTM, 2004a) for concrete made with Type I cement. Thus, by measuring setting times at two extreme temperatures, it is possible to estimate setting time for any temperature within the extremes.

21.2.7.5 Highway Applications

In 2000, the Pennsylvania Transportation Institute conducted a survey of state departments of transportation to establish progress in the adoption of the maturity method (Tikalsky et al., 2001). Of the 44 states that responded to the survey, 32 indicated that they had conducted or were conducting research on implementing the method. The reported uses of the maturity method included determination of formwork removal times, determination of joint sawing times, and determination of opening times for pavements. Some states, such as Texas (TDOT, 2002), South Dakota (SDDOT, 1999), Iowa (IDOT, 2002),

and Indiana (INDOT, 1999), developed their own test methods, based essentially on ASTM C 1074. Some of these methods were developed for estimating in-place flexural strength and others were applicable to either flexural or compressive strengths. All protocols use the temperature–time factor (Equation 21.1) as the maturity function. State department of transportation protocols include procedures for verifying during construction that previously established strength–maturity relationships are valid. Texas, for example, requires monitoring the temperature–time factor of selected specimens molded from samples of field concrete. At a preestablished level of maturity, the specimens are tested for strength. The measured strengths are compared with the estimated strength based on the strength–maturity relationship. If the difference between measured and estimated strengths is greater than 10%, a new strength–maturity relationship must be established for the project. The Texas protocol also requires enhanced batch plant inspection when the maturity method is used to estimate in-place strength.

21.2.8 Statistical Methods

In 1983, ACI Committee 318 recognized in-place test methods as alternatives to testing field-cured cylinders for assessing concrete strength during construction. The following sentence was added to Section 6.2.1.1 of ACI 318-83, dealing with evaluation of in-place strength before form removal: “Concrete strength data may be based on tests of field-cured cylinders or, when approved by the Building Official, on other procedures to evaluate concrete strength.” The Commentary to ACI 318-03 listed acceptable alternative procedures and further stated that these alternative methods “require sufficient data using job materials to demonstrate correlation of measurements on the structure with compressive-strength of molded cylinders or drilled cores.” Thus, to use the alternative methods, an empirical relationship has to be developed to convert in-place test results to estimated compressive-strength values. In addition, a procedure is required to analyze in-place test results so compressive strength can be estimated with a high degree of confidence. The latter issue is not mentioned in ACI 318. The report of ACI Committee 228 (2003) provides information on developing the **strength relationship**^{*} and how it should be used to estimate the in-place strength. Basically, the procedure is to perform in-place tests (X values) and standard compressive strength tests (Y values) on companion specimens at different levels of strength and use regression analysis to determine a best-fit curve ($Y = f(X)$) to the data. The relationship that is obtained and the results of in-place tests on the structure are used to estimate the concrete strength in the structure. To obtain a reliable estimate of the in-place strength, statistical methods are necessary to account for the various sources of uncertainty. The procedures that can be used for this purpose are reviewed in this section after a brief review of recent developments related to statistical analysis.

21.2.8.1 Background

During the 1960s and 1970s, the traditional method of ordinary least squares (OLS) analysis was used to analyze correlation data and establish the best-fit equation for the strength relationship and its confidence limits (Natrella, 1963). In the 1980s, simple procedures were used to estimate lower confidence limits of estimated in-place strength (Bickley, 1982b; Hindo and Bergstrom, 1985). It was recognized that the existing methods were not statistically rigorous and the stated confidence levels were not accurate (Stone et al., 1986). One of the deficiencies inherent in using OLS to establish the strength relationship is that OLS assumes that the X variable (the in-place test result) has no measurement error. In fact, the within-test coefficient of variation of in-place tests can be two to three times greater than those of compression tests of cores or cylinders. To overcome these deficiencies, a study was undertaken at the National Institute of Standards and Technology (NIST) to develop a rigorous method for obtaining the strength relationship and for estimating the lower confidence limit of the in-place strength (Stone and Reeve, 1986). The procedure that was developed used a method for least-squares fitting that accounted for error in the X variable (Mandel, 1984). The rigorous method was discussed in the original report of

^{*} The term *strength relationship* refers to the empirical equation, obtained from a correlation testing program, that relates the compressive strength (or other measure of strength) of concrete to the quantity measured by the in-place test.

ACI Committee 228 (1989), but it found little use due to its complexity. Subsequently, a simplification of the rigorous method was proposed that could be implemented by using a computerized spreadsheet (Carino, 1993). This simplified method was incorporated into the 1995 revision of the ACI Committee 228 report and is retained in the current version. A step-by-step procedure for implementing the method is included in the appendices to the report. That procedure was later incorporated into a stand-alone computer program (Chang and Carino, 1998).

During the late 1980s and early 1990s, A. Leshchinsky published a series of papers on statistical methods for in-place tests that were based largely on work at the Institute for Research of Building Structures in Kiev. These papers compared practices in different countries with those in the former Soviet Union, which had a long history in using in-place methods for quality control in precast concrete plants. In a review of various national standards, Leshchinsky (1990) concluded that:

- Greater numbers of in-place tests are required compared with tests of standard specimens, which makes in-place testing economically unattractive.
- The number of test specimens necessary to establish the strength relationship and the number of in-place tests on the structure have been established arbitrarily, based on the experiences of those writing the standards.
- The number of replicate tests to establish the strength relationship differs from the replications at a test location in a structure.

Leshchinsky presented procedures for selecting in-place tests based on consideration of cost and reliability of the estimated strength, as well as recommendations for reducing the cost of in-place testing.

In another paper, procedures for developing correlations were discussed and criteria were suggested for verifying the correlation at periodic intervals (Leshchinsky and Leshchinsky, 1991). The notion of a **stable correlation** was introduced. This refers to a strength relationship that is affected little by changes in concrete composition and the construction process. It was noted that methods that have a close connection between concrete strength and the quantity measured by the in-place test tend to have more stable correlations, but they also tend to be more costly than the methods that do not have this close connection. Pullout, break-off, and pull-off tests were identified as possessing stable correlations. It was also shown that the correlations may be affected by the location on the test specimens (top, middle, bottom) where the in-place test is performed (Leshchinsky, 1991a). Leshchinsky also discussed factors to consider when deciding whether or not combined methods are justified (Leshchinsky, 1991b). In addition, the following situations were identified where the combined use of a reliable, expensive method could be combined with a less expensive but less reliable method to achieve an overall cost savings in testing:

- The more reliable method is used to calibrate the strength relationship of the less reliable method; a correction factor is determined and applied to the strength estimated by the less reliable method.
- The less reliable method is used to identify areas of lower quality concrete where the more reliable tests should be performed.
- For new construction, a less reliable method is used to determine when tests by the more reliable method should be performed.

An example of such a combined approach is the use of inexpensive disposable maturity meters in combination with pullout tests. The maturity meter is used as an estimator of when the in-place concrete has reached target strength, and pullout tests are then done to confirm that the target strength has in fact been attained.

In a few instances in North America in-place testing has been used for acceptance testing. The major barrier is the lack of a consensus-based, statistical procedure for this application. Leshchinsky (1992) discussed some of the considerations for using in-place testing for acceptance testing. Because the strength of the actual concrete in the structure is measured, the acceptable in-place strength could be less than the design strength. Leshchinsky also reviewed provisions in existing national standards that allow acceptance based on in-place tests. In some of these standards, the required in-place strength depends

on the number of tests and the variability of the in-place results. For high variability, the required in-place strength might exceed the design strength. ACI Committee 228 (2003) provided the following proposal for acceptance of concrete based on in-place testing:

The concrete in a structure is acceptable if the estimated average, in-place, compressive strength based on a reliable in-place test procedure equals at least 85 percent of f'_c and no test result estimates the compressive strength to be less than 75 percent of f'_c .

These criteria are based on the ACI 318 acceptance criteria for core strengths. The ACI Committee 228 report stated that the implementation of such criteria requires a consensus-based standard practice for statistical analysis of in-place test results.

21.2.8.2 Correlation Testing

The following is a summary of the guidelines provided in the ACI Committee 228 (2003) report for establishing the strength relationship for a specific job. The procedure differs depending on whether in-place testing will be used to estimate strength during construction or in an existing structure. For new construction, the strength relationship is established from a laboratory testing program performed before using the in-place test method in the field. Companion test specimens are made using the same concreting materials to be used in construction. At regular intervals, measurements are made using the in-place test methods, and the corresponding compressive strengths of standard specimens are also measured. The number of strength levels has a significant effect on the confidence limits of the strength relationship. It is recommended that at least six strength levels be used to establish the strength relationship. More than about nine strength levels may not be economically justified. The strength levels should be evenly spaced to obtain an unbiased estimate of the strength relationship. The range of strengths in the correlation testing must include the range of strengths that are to be estimated in the structure.

For some techniques, such as rebound number and pulse velocity, it is possible to perform the in-place test on standard specimens without damaging them, and the same specimens can be tested subsequently for compressive strength. For other methods that result in local damage, in-place tests are carried out on separate specimens. It is important for the in-place tests and standard tests to be performed on specimens having similar compaction and that companion tests be performed at the same maturities. Curing companion test specimens in the same water bath is a convenient way to obtain similar temperature histories. Alternatively, internal temperatures can be recorded and test ages can be adjusted so in-place tests and standard tests are performed at the same maturity index for each strength level.

For existing construction, the strength relationship is established by performing in-place tests on the structure and determining the compressive strength from cores taken at adjacent locations. To obtain a wide range of strengths, a rebound hammer or pulse velocity survey may be performed first to identify locations with apparently different quality. At each test location, at least two cores should be taken to evaluate the compressive strength. Thus, the proper application of in-place testing for existing construction requires taking at least 12 cores to establish the strength relationship. As a result, the use of in-place testing may be economical only when large volumes of concrete are to be evaluated.

Additional information on the number of replicate in-place tests and the companion test specimens to use for different test methods may be found in the ACI Committee 228 report (2003). After paired values of average in-place test results and average compressive strengths are obtained, regression analysis is used to establish the equation of the strength relationship. The ACI 228 report recommends that linear regression be done using the natural logarithms of the test results so the following equation is fitted:

$$\ln C = a + b \ln I \quad (21.14)$$

where:

- $\ln C$ = average of natural logarithms of compressive strengths.
- $\ln I$ = average of natural logarithms of in-place test results.
- a = intercept of line.
- b = slope of line.

The report also recommends that the regression analysis to determine the values of a and b be performed using a procedure that accounts for the error in the X variable (in-place test results). This procedure is explained in detail in the appendix of ACI 228.1R. Basically, the ratio of the variances of the in-place test results and compressive strength results is used to define a parameter (λ), which is applied to the equations of ordinary least-squares regression to obtain the slope and intercept. This approach results in a more reliable estimate of the uncertainty of the strength relationship.

21.2.8.3 In-Place Strength Estimate

When making estimates of the in-place strength, the user should consider several important points:

- Where should the in-place tests be performed?
- How many in-place tests should be performed?
- How should the data be analyzed to obtain a reliable estimate of in-place strength?

These points are also covered in ACI 228.1R. In the case of new construction, a preconstruction meeting should be held to establish where and how many in-place tests should be performed. ACI 228.1R provides guidelines that can be used as a starting point to arrive at these decisions. For existing construction, a pretesting meeting should be held among all parties who share an interest in the test results. Agreement should be reached on the procedures for obtaining, analyzing, and interpreting the test results.

After the in-place test results have been obtained, statistical analysis is used to arrive at a reliable estimate of the in-place concrete strength. The term *reliable estimate* means that there should be a high likelihood that the actual in-place strength exceeds the estimated strength. The statistical procedure that is used should account for the following principal sources of uncertainty or variability:

- The uncertainty of the strength relationship
- The variability of the in-place test results
- The variability of the in-place concrete strength

ACI 228.1R includes several approaches that may be used for this purpose. One of these is based on the simplification by Carino (1993) of the rigorous procedure developed earlier by National Institute of Standards and Technology (NIST) researchers (Stone and Reeve, 1986). The underlying steps of this simplified procedure are illustrated in Figure 21.12. The average of the in-place test results is used to estimate the average concrete strength using a strength relationship. Next, the lower confidence limit of the average concrete strength is obtained by taking into account the uncertainty of the estimate from the strength relationship. This uncertainty includes a component based on the correlation testing and a component based on the variability of the in-place test results. Finally, the variability of the in-place concrete strength is used to obtain the tenth-percentile strength—that is, the strength expected to be exceeded by 90% of the concrete in the structure. This latter variability is estimated using the assumption that the ratio of the standard deviation of compressive strength tests to the standard deviation of in-place test results has the same value in the field as was obtained during the correlation testing (Stone and Reeve, 1986). The details for applying this procedure are given in ACI 228.1R (ACI Committee 228, 2003), and additional background information may be found in Carino (1993). This procedure has been implemented in a Windows-based computer program (Chang and Carino, 1998) that may be obtained by contacting the author of this chapter.

21.3 Methods for Flaw Detection and Condition Assessment*

21.3.1 Introduction

Other types of NDT methods are those used for flaw detection and condition assessment. In this context the term *flaw* include voids, honeycombing, delaminations, cracks, lack of sub-base support, and so forth. Since the 1980s, research and development efforts for these methods have exceeded those for methods

* Some of text in this section is based on a draft prepared by the author for the report on NDT methods subsequently developed by ACI Committee 228 (1998).

FIGURE 21.12 Schematic of statistical procedure for reliable estimate of in-place compressive strength. (From Carino, N.J., in *New Concrete Technology: Robert E. Philleo Symposium*, ACI SP-141, American Concrete Institute, Farmington Hills, MI, 1993, pp. 39–64.)

to estimate strength. The research impetus has come primarily from the transportation industry, because much of the highway infrastructure is in need of repair as a result of natural aging or the damage resulting from corrosion of reinforcing steel or deterioration of concrete. The techniques for flaw detection are based generally on the following simple principle: The presence of an internal anomaly interferes with the propagation of certain types of waves. By monitoring the response of the test object when it is subjected to these waves, the presence of the anomaly can be inferred. The interpretation of the results of these types of NDT methods usually requires an individual who is knowledgeable both in concrete technology and in the physics governing the wave propagation. This section of the chapter reviews the following techniques:

- Visual inspection
- Stress-wave propagation methods
- Infrared thermography
- Ground-penetrating radar
- Electrical/magnetic methods
- Nuclear methods

Emphasis is placed on explaining the underlying principles of the methods, and the reader may find additional information in the ACI Committee 228 report (1998), Malhotra and Carino (2004), and Bungey and Millard (1996).

21.3.2 Visual Inspection

Visual inspection is one of the most versatile and powerful of the NDT methods, and it is typically one of the first steps in the evaluation of a concrete structure (Perenchio, 1989). Visual inspection can provide a wealth of information that may lead to positive identification of the cause of observed distress. Its effectiveness depends, however, on the knowledge and experience of the investigator. Broad knowledge in structural engineering, concrete materials, and construction methods is required to extract the most information from visual inspection. Useful guides are available to assist less experienced individuals in recognizing different types of damage and determining the probable cause of the distress (ACI Committee 201, 1992; ACI Committee 207, 1994; ACI Committee 224, 2007; ACI Committee 362, 1997).

Before performing a detailed visual inspection, the investigator should develop and follow a definite plan to maximize the quality of the recorded data. Various ACI documents should be consulted for additional guidance on planning and carrying out the complete investigation (ACI Committee 207, 1994; ACI Committee 224, 2007; ACI Committee 362, 1997; ACI Committee 437, 2003). A typical investigation might involve the following activities:

- Perform a walk-through visual inspection to become familiar with the structure.
- Gather background documents and information on the design, construction, maintenance, and operation of the structure.
- Plan the complete investigation.
- Perform a detailed visual inspection.
- Perform any necessary sampling or in-place tests.

21.3.2.1 Supplemental Tools

Visual inspection has the obvious limitation that only visible surfaces can be inspected. Internal defects go unnoticed, and no quantitative information is obtained about the properties of the concrete. For these reasons, a visual inspection is usually supplemented by one or more of the other NDT methods discussed in this chapter. The inspector should consider other useful tools that can enhance the power of a visual inspection. Optical magnification allows a more detailed view of local areas of distress. Available instruments range from simple magnifying lenses to more expensive hand-held microscopes. Some fundamental principles of optical magnification can help in selecting the correct tool. The focal length decreases with increasing magnifying power, which means that the primary lens must be placed closer to the surface being inspected. The field of view also decreases with increasing magnification, making it tedious to inspect a large area at high magnification. The depth of field is the maximum difference in elevation of points on rough textured surface that are simultaneously in focus; this also decreases with increasing magnification of the instrument. To ensure that the “hills” and “valleys” are in focus simultaneously, the depth of field has to be greater than the elevation differences in the texture of the surface that is being viewed. Finally, the illumination required to see clearly increases with magnification level, and artificial lighting may be required at high magnification.

A very useful tool for crack inspection is a small hand-held magnifier with a built-in measuring scale on the lens closest to the surface being viewed (ACI Committee 224, 2007). With such a crack comparator, the width of surface opening cracks can be measured accurately. A stereo microscope includes two viewing lenses that provide a three-dimensional view of the surface. By calibrating the focus-adjustment screw, the investigator can estimate the elevation differences in surface features.

Fiberscopes and borescopes allow inspection of regions that are otherwise inaccessible to the naked eye. A fiberscope is composed of a flexible bundle of optical fibers and a lens system, and it allows cavities within a structure to be viewed by means of small access holes. The fiberscope is designed so some fibers transmit light to illuminate the cavity. In some systems, the operator can rotate the viewing head to allow a wide viewing angle from a single access hole. A borescope is composed of a rigid tube with mirrors and lenses and is designed to view straight ahead or at right angles to the tube. The image is clearer using a borescope, but the fiberscope offers more flexibility in the field of view. Use of these scopes requires drilling small holes if other access channels are absent, and the holes must intercept the cavity to be inspected. Some methods discussed in the remainder of the chapter may be used to locate these cavities; hence, the fiberscope or borescope may be used to verify the results of other NDT methods without removing cores.

A recent development that expands the flexibility of visual inspection is the small digital video camera. These are used in a manner similar to borescopes, but they offer the advantage of a video output that can be displayed on a monitor or stored on appropriate recording media. These charge-coupled device (CCD) cameras come in a variety of sizes, resolutions, and focal lengths. Miniature versions as small as 12 mm in diameter, with a resolution of 460 scan lines, are available. They can be inserted into holes drilled into the structure for views of internal cavities, or they can be mounted on robotic devices for inspections in pipes or areas with biological hazards.

In summary, visual inspection is a powerful NDT method. Its efficiency, however, is governed largely by the experience and knowledge of the investigator. A broad knowledge of structural behavior, materials, and construction methods is desirable. Visual inspection is typically one aspect of the total evaluation plan, which will often be supplemented by a series of other NDT methods or invasive procedures.

21.3.3 Stress-Wave Propagation Methods

Tapping an object with a hammer or steel rod (sounding) is one of the oldest forms of nondestructive testing based on stress-wave propagation. Depending on whether the response is a high-pitched **ringing** sound or a low-frequency **rattling** sound, the integrity of the member can be assessed. The method is subjective, as it depends on the experience of the operator, and it is limited to detecting near-surface defects. Despite these inherent limitations, **sounding** is a useful method for detecting near-surface delaminations, and it has been standardized by ASTM (Test Method D 4580; see ASTM, 2003a).

In NDT of metals, the **ultrasonic pulse-echo** (UP-E) method is a reliable method for locating small cracks and other defects. The principle of UP-E is similar to sonar. An electromechanical transducer is used to generate a short pulse of ultrasonic stress waves that propagates into the object being inspected. Reflection of the stress pulse occurs at boundaries separating materials with different densities and elastic properties (these determine the acoustic impedance of a material). The reflected pulse travels back to the transducer, which also acts as a receiver. The received signal is displayed on an oscilloscope or other display device, and the round-trip travel time of the pulse is measured electronically. By knowing the speed of the stress waves, the distance to the reflecting interface can be determined. In the absence of an internal defect, the opposite face of the test object is detected.

Early attempts to use UP-E equipment designed for metal inspection to test concrete were unsuccessful because of the heterogeneous nature of concrete. The presence of paste–aggregate interfaces, air voids, and reinforcing steel result in a multitude of echoes that obscure those from real defects. In the late 1990s and early 2000s, however, significant progress was made in using special ultrasonic transducers and a signal-processing method known as the *synthetic aperture focusing technique* (SAFT) to reconstruct internal images of concrete test objects (Kozlov et al., 2006; Krause et al., 2006; Schickert et al., 2003).

Beginning in the 1980s, considerable progress has been made in the development of usable techniques based on the propagation of impact-generated stress waves. This section reviews the basic concepts of stress-wave propagation due to impact and reviews the principles of some of the more promising impact-based methods. A more comprehensive review is provided by Carino (2004c).

21.3.3.1 Basic Relationships

When a disturbance (stress or displacement) is applied suddenly at a point on the surface of a solid, such as by impact, the disturbance propagates through the solid as three different waves: a P-wave, an S-wave, and an R-wave. The P-wave and S-wave propagate into the solid along spherical wavefronts. The P-wave is associated with the propagation of normal stress, and the S-wave is associated with shear stress. In addition, an R-wave travels away from the disturbance along the surface. In an infinite isotropic, elastic solid, the P-wave speed (C_p) is related to the Young's modulus of elasticity (E), Poisson's ratio (ν), and the density (ρ) as follows (Krautkrämer and Krautkrämer, 1990):

$$C_p = \sqrt{\frac{E(1-\nu)}{\rho(1+\nu)(1-2\nu)}} \quad (21.15)$$

The S-wave propagates at a slower speed (C_s) given by:

$$C_s = \sqrt{\frac{G}{\rho}} = \sqrt{\frac{E}{\rho 2(1+\nu)}} \quad (21.16)$$

where G is the shear modulus of elasticity.

The ratio of S-wave speed to P-wave speed depends on Poisson's ratio, as follows:

$$\frac{C_S}{C_P} = \sqrt{\frac{1-2\nu}{2(1-\nu)}} \quad (21.17)$$

For a Poisson's ratio of 0.2, which is typical of concrete, this ratio equals 0.61. The ratio of the R-wave speed (C_R) to the S-wave speed is given by the following approximate formula:

$$\frac{C_R}{C_S} = \frac{0.87+1.12\nu}{1+\nu} \quad (21.18)$$

For Poisson's ratio equal to 0.2, the R-wave travels at 92% of the S-wave speed.

In the case of bounded solids, the wave speed is also affected by the geometry of the solid. For rod-like solids, the P-wave speed is independent of Poisson's ratio and is given by the following:

$$C_P = \sqrt{\frac{E}{\rho}} \quad (21.19)$$

Thus, for $\nu = 0.2$, the wave speed in a slender rod is about 5% slower than in a large solid.

When a stress wave traveling through material 1 is incident on the interface between a dissimilar material 2, a portion of the incident wave is reflected. The amplitude of the reflection is a function of the angle of incidence and is a maximum when this angle is 90° (normal incidence). For normal incidence, the reflection coefficient, R , is given by the following:

$$R = \frac{Z_2 - Z_1}{Z_2 + Z_1} \quad (21.20)$$

where:

Z_2 = specific acoustic impedance of material 2.

Z_1 = specific acoustic impedance of material 1.

The specific acoustic impedance is the product of the wave speed and density of the material. The following are approximate Z values for P-wave reflection in some materials (Carino, 2004c):

Material	Specific Acoustic Impedance, kg/(m ² s)
Air	0.4
Water	1.5×10^6
Soil	$0.3 \text{ to } 4 \times 10^6$
Concrete	$7 \text{ to } 10 \times 10^6$
Steel	47×10^6

Thus, it can be shown that when a stress wave traveling through concrete encounters an interface with air, there is almost total reflection at the interface. This is why NDT methods based on stress-wave propagation have proven to be successful for locating defects within concrete.

21.3.3.2 Impact Methods

The greatest success in the practical application of stress-wave methods for testing concrete has been to use mechanical impact to generate the stress pulse. Impact causes a high-energy pulse that results in high penetration of the stress waves. Several techniques have been developed that are similar in principle but differ in the specific instrumentation and signal-processing methods that are used (Davis and Dunn, 1974; Davis and Hertlein, 1991; Higgs, 1979; Nazarian and Stokoe, 1986a; Sansalone and Carino, 1986; Stain, 1982; Steinbach and Vey, 1975).

FIGURE 21.13 Schematic of test using impact to generate stress waves.

Figure 21.13 provides a schematic of an impact test. The principle is analogous to other echo methods that have been discussed. Impact on the surface produces a disturbance that travels into the object along spherical wavefronts as P- and S-waves. In addition, a surface wave (R-wave) travels away from the impact point. The P- and S-waves are reflected by internal defects (difference in elastic constants and density) or external boundaries. When the reflected waves, or echoes, return to the surface, they produce displacements that are measured by a receiving transducer. If the transducer is placed close to the impact point, the response is dominated by P-wave echoes (Sansalone and Carino, 1986). Using **time-domain** analysis, the time from the start of the impact to the arrival of the P-wave echo is measured, and the depth of the reflecting interface can be determined if the P-wave speed is known. The first successful applications of time-domain impact methods were in the field of geotechnical engineering to evaluate the integrity of concrete piles and caissons (Davis and Dunn, 1974; Steinbach and Vey, 1975). The technique is known as the *sonic-echo* or *seismic-echo* method. The long length of foundation structures allows sufficient time separation between the generation of the impact and the echo arrival, and determination of round-trip travel times is relatively simple (Lin et al., 1991b; Olson and Church, 1986).

The impact response of thin concrete members, such as slabs and walls, is more complicated than that of long slender members. Work by Sansalone and Carino (1986) led to the development of a successful technique for flaw detection in relatively thin concrete structures. The technique is known as the *impact-echo* method (Sansalone and Street, 1997). A key development leading to the success of the impact-echo method was the use of **frequency analysis**, instead of time-domain analysis, of the recorded waveforms (Carino et al., 1986; Sansalone, 1997). The principle of frequency analysis is as follows: The P-wave produced by the impact undergoes multiple reflections between the testing surface and the reflecting interface. Each time the P-wave arrives at the testing surface, it causes a characteristic displacement. Thus, the recorded waveform has a periodic pattern that depends on the frequency (f) of the P-wave arrival, which is given by:

$$f = \frac{C_p}{2D} \quad (21.21)$$

where C_p is the P-wave speed* and D is the depth of the reflecting interface. This frequency is termed the *thickness frequency*.

* Studies by Sansalone et al. (1997a) have shown that the P-wave speed in impact-echo testing of plate-like structures is approximately 96% of the P-wave speed in an infinite solid.

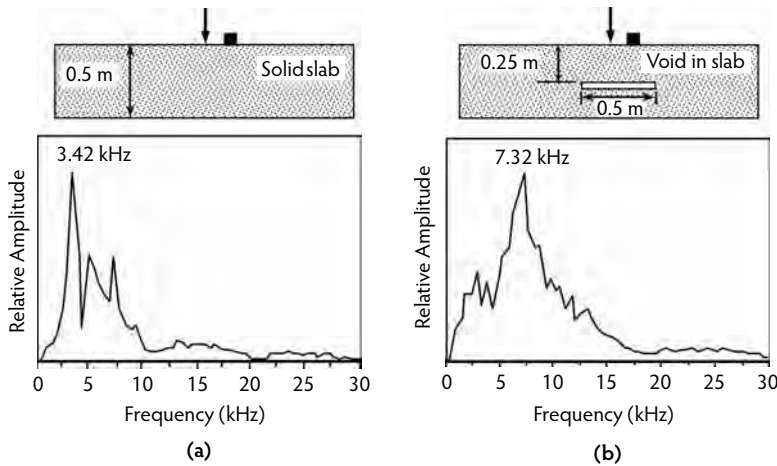

FIGURE 21.14 Examples of amplitude spectra from impact-echo test of concrete slab: (a) solid slab, and (b) slab with void.

To apply frequency analysis, the recorded waveform is transformed into the frequency domain by using the fast Fourier transform technique (Bracewell, 1978). The computed amplitude spectrum shows the frequency components in the waveform. For plate-like structures, the thickness frequency will usually be the dominant peak in the spectrum. The frequency value of the peak in the amplitude spectrum can be used to determine the depth of the reflecting interface by expressing Equation 21.21 as follows:

$$D = \frac{C_p}{2f} \quad (21.22)$$

Figure 21.14 illustrates the use of frequency analysis to interpret impact-echo tests. Figure 21.14a shows the amplitude spectrum from a test over a solid portion of a 0.5-m-thick concrete slab. There is a frequency peak at 3.42 kHz, which corresponds to multiple P-wave reflections between the bottom and top surfaces of the slab. Using Equation 21.21 or Equation 21.22 and solving for C_p , the P-wave speed is calculated to be 3420 m/s. Figure 21.14b shows the amplitude spectrum from a test over a portion of the slab containing an artificial disk-shaped void (Carino and Sansalone, 1989b). The peak at 7.32 kHz results from multiple reflections between the top of the slab and the void. Using Equation 21.21, the calculated depth of the void is $3420/(2 \times 7320) = 0.23$ m, which compares favorably with the planned distance of 0.25 m.

In the initial work leading to the impact-echo method (Sansalone and Carino, 1986), it was noted that the duration of the impact was critical to determining the success of the method. As shown in Figure 21.13, the force–time relationship for the impact may be approximated as a half-cycle sine curve, and the duration of the impact is the **contact time**. The contact time determines the frequency content of the stress pulse generated by the impact (Carino et al., 1986). As an approximation, the highest frequency component of significant amplitude equals the inverse of the contact time. To accurately locate shallow defects, the stress pulse must have frequency components greater than the frequency corresponding to the flaw depth (Equation 21.21). For example, for a P-wave speed of 4000 m/s, a pulse with a contact time shorter than 100 μ s is needed to measure the depth of defects shallower than about 0.2 m. Various impact sources have been used for impact testing. In evaluation of piles, hammers can be used to produce energetic impacts with long contact times (on the order of 1 ms). Such impacts are acceptable for testing long, slender structures but not for slabs or walls. For testing slabs from 0.15 to 0.5 m thick, steel balls and spring-loaded spherically tipped impactors have been used successfully. Steel balls are convenient impact sources because the contact time is proportional to the diameter of the ball (Goldsmith, 1965).

The impact-echo method has been successful in detecting a variety of defects (Carino, 2004c; Sansalone, 1997; Sansalone and Street, 1997). These defects include voids and honeycombed concrete in members, delaminations in bare and overlaid slabs, and voids in tendon ducts (Carino and Sansalone, 1992; Jaeger et al., 1996; Sansalone and Carino, 1986, 1988, 1989a,b). Experimental studies have been supplemented with analytical studies to gain a better understanding of the propagation of transient waves in bounded solids with and without flaws (Cheng and Sansalone, 1993a,b, 1995a,b; Lin et al., 1991a,b; Sansalone and Carino, 1987). Application of the impact-echo method has been extended to prismatic members, such as columns and beams (Lin and Sansalone, 1992a,b,c). It has been found that reflections from the perimeter of these members cause complex modes of vibration. As a result, the amplitude spectra have many peaks, and the depth of the member is not related to the dominant frequency in the spectrum according to Equation 21.21. Nevertheless, it has been shown that defects can be detected within beams and columns, and a successful field application has been reported (Sansalone and Poston, 1992). The impact-echo method has also been applied to evaluate the quality of the bond between an overlay and base concrete (Lin and Sansalone, 1996a,b). The method has also been found applicable to masonry walls (Williams et al., 1997).

As with most methods for flaw detection in concrete, experience is required to interpret stress-wave test results. To assist users in the interpretation of impact-echo results from tests of plate-like structures, an artificial intelligence technique known as a *neural network* (Sansalone et al., 1991) was investigated. In this technique, a computer program is **trained** to recognize amplitude spectra associated with flawed and unflawed structures. After this training, the program can be used to classify the results of tests on a structure under investigation. This technique was incorporated into the first commercial impact-echo test system (Pratt and Sansalone, 1992). It was found, however, that this “black box” approach was not successful because users relied blindly on the results of the neural network analysis without considering the validity of the recorded waveforms. Invalid waveforms can result from poor coupling of the receiver or an improper impact. Visual inspection of recorded waveforms by a trained operator will reveal invalid waveforms, which should be discarded, and a new test should be performed at that point.

In 1998, ASTM adopted a test method on the use of the impact-echo method to measure the thickness of plate-like concrete members (Carino, 2004c). For the purpose of this test method, a *plate* is defined as a structure or portion of a structure in which the lateral dimensions are at least six times the thickness. ASTM Test Method C 1383 (ASTM, 2004b) includes two procedures. Procedure A is used to measure the P-wave speed in the concrete. This measurement is based on measuring the travel time of the P-wave between two transducers a known distance apart. The background research for this technique is provided in Sansalone et al. (1997a,b) and Lin and Sansalone (1997). Procedure B determines the thickness frequency using the impact-echo method from which the plate thickness is calculated using the measured P-wave speed and Equation 21.22. As explained by Sansalone et al. (1997a), the P-wave speed obtained by Procedure A is multiplied by 0.96 when Equation 21.22 is used to calculate thickness. The data analysis procedure in ASTM C 1383 considers the systematic errors associated with the digital nature of the data in Procedures A and B. The thickness is reported with an uncertainty that is related to the sampling interval in Procedure A and the duration of the recorded signal in Procedure B (Sansalone et al., 1997a,b). Limited comparisons with the length of drilled cores demonstrated that pavement thickness based on impact-echo results were within 3% of core lengths (Sansalone and Streett, 1997; Sansalone et al., 1997a).

In the 2000s, extensive investigations to improve the capabilities of the impact-echo method were carried out in different countries. These studies have focused on developing scanning systems to increase the speed of impact-echo testing and exploring different signal analysis techniques to improve data presentation and interpretation. In a 2006 conference on NDT in civil engineering, 12 papers dealt with various aspects of impact-echo testing (Al-Qadi and Washer, 2006). The main themes of these papers were signal analysis, thickness measurement, and detection of voids in grouted tendon ducts.

Another type of impact method is known as *impulse–response*, *transient dynamic response*, or *impedance testing* (Davis and Dunn, 1974; Davis and Hertlein, 1991; Higgs, 1979; Olson and Wright, 1990; Stain,

FIGURE 21.15 Idealized mobility plot of a pile in soil. (Adapted from Davis, A.G. and Dunn, C., *Proc. Inst. Civ. Eng.*, 57(Part 2), 571–593, 1974.)

1982). In this approach, the force history of the impact and the response of the structure are measured. Through a signal-processing technique, the measured response and force history are used to compute the characteristic impulse response spectrum of the structure (Carino, 2004c). The impulse–response spectrum of a structure depends on its geometry, the support conditions, and the existence of flaws or cracks.

Depending on the measured quantity of the structural response (displacement, velocity, or acceleration), the impulse–response spectrum has different meanings. Typically, velocity is measured and the resulting impulse–response spectrum has the units of velocity/force, which is referred to as *mobility*. The spectrum of mobility vs. frequency is called a *mobility plot*. Figure 21.15 is an idealized mobility plot for a pile embedded in soil (Davis and Dunn, 1974). At frequency values corresponding to resonant frequencies of the structure, mobility values are maximum. The series of peaks represents the fundamental and higher longitudinal modes of vibration. The difference between any two adjacent peaks (Δf) is equal to the fundamental longitudinal resonant frequency (Higgs, 1979). The length of the pile can be calculated by using Δf in place of f in Equation 21.22.

In addition to length, other information can be obtained from impulse–response tests on pile structures (Davis and Dunn, 1974; Finno and Gassman, 1998). At low frequencies, the pile and soil vibrate together, and the mobility plot provides information on the dynamic stiffness of the soil–pile structure (Davis and Dunn 1974; Stain, 1982). In this low-frequency range, the mobility plot is approximately a straight line, and the inverse of the slope of the straight line represents the dynamic stiffness of the pile head. Thus, mobility plots with steeper initial slopes correspond to less dynamic stiffness of the pile head. The pile head stiffness is a function of the dynamic stiffness of the pile itself and the properties of the surrounding soil.

Application of the impulse–response method has been extended to testing of plate-like structures such as pavements, floor slabs, walls, concrete tanks, and various type of cladding materials (Davis, 2003; Davis and Hertlein, 1987, 1990; Davis et al., 1997; Nazarian and Reddy, 1996; Nazarian et al., 1994). The following indices obtained from mobility plots have been found to correlate with different conditions:

- *Average mobility from 100 to 800 Hz*—The average mobility is affected by the stiffness of the concrete, the thickness of the plate, and the support conditions.
- *Mobility slope from 100 to 800 Hz*—The mobility slope, which is obtained from the slope of the best-fit line to the mobility values between 100 and 800 Hz, has been found to be related to the degree of consolidation of the concrete. For well-consolidated concrete, the mobility has a nearly constant value over this frequency range (Nazarian and Reddy, 1996). Poorly consolidated concrete, on the other hand, shows increasing mobility with frequency. These different behaviors are illustrated in Figure 21.16a.

FIGURE 21.16 Examples of mobility plots from impulse-response tests of plate-like structures: (a) high mobility slope indicative of poor consolidation, and (b) high peak at low frequency indicative of a delamination or void below slab on ground. (Adapted from Germann Instruments, Inc., *NDT Systems*, Catalog NDT-2007, www.germann.org.)

- *Ratio of peak mobility to average mobility from 100 to 800 Hz*—When there is a delamination or local loss of support for a slab on ground, there will be a high mobility at low frequency. This corresponds to high amplitude flexural vibration of a plate supported at its edges. Thus, a high ratio of the peak mobility to the average mobility in the range of 100 to 800 Hz can be used as an indication of a delamination or loss of subgrade support (Davis and Hertlein, 1987). This behavior is illustrated in Figure 21.16b.

For plate-like structures, impulse-response testing is done at points on a grid laid out on the exposed surface. The results are analyzed on a comparative basis by using contour plots of one or more of the above indices. Anomalous regions in the contour plots are indicators of locations that require more in depth investigation. Impulse-response testing is more rapid than manual impact-echo testing, so the two methods are usually used in combination for cost-effective investigations of the plate-like structures. Impulse-response testing is done at a coarse grid spacing to identify potentially anomalous regions, which may be investigated further using impact-echo testing.

21.3.3.3 Spectral Analysis of Surface Waves

In the late 1950s and early 1960s, Jones (1955, 1962) reported on the use of **surface waves** to determine the thickness and elastic stiffness of pavement slabs and the underlying layers. The method involved determining the relationship between the wavelength and velocity of surface waves as the vibration frequency was varied. Apart from the studies by Jones, there seems to have been little use of this technique for testing concrete pavements. In the early 1980s, however, researchers at The University of Texas at Austin began studies of a surface-wave technique that involved an impactor instead of a steady-state vibrator. Digital signal processing was used to develop the relationship between wavelength and velocity. The technique is referred to as *spectral analysis of surface waves* (SASW) (Heisey et al., 1982; Nazarian et al., 1983). Figure 21.17 shows the configuration for SASW testing (Nazarian and Stokoe, 1986a). Two receivers are used to monitor the movement of the surface due to the R-wave produced by the impact. The received signals are processed, and a back-calculation scheme is used to infer the stiffnesses of the underlying layers.

Just as an impact is composed of a range of frequency components, the R-wave produced by a given impact also contains a range of components of different frequencies or wavelengths. (Note that the product of frequency and wavelength equals wave speed.) This range depends on the contact time of the impact; a shorter contact time results in a broader range. The lower frequency (longer wavelength)

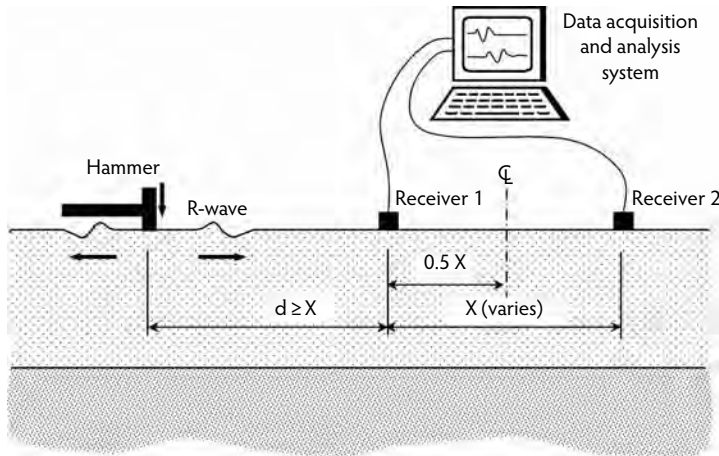

FIGURE 21.17 Schematic of testing configuration for spectral analysis of surface waves (SASW) technique.

components penetrate more deeply, and this is the key to using the R-wave to gain information about the properties of the underlying layers (Rix and Stokoe, 1989). In a layered system, the speed of these different wavelength components is affected by the wave speed in the layers through which the components travel. A layered system is a **dispersive** medium for R-waves, which means that different frequency components in the R-wave travel at different speeds, which are called *phase velocities* (Krstulovic-Opara et al., 1996).

In the SASW method, phase velocities are calculated by determining the time it takes for each frequency (or wavelength) component to travel between the two receivers. These travel times are determined from the phase difference of the frequency components arriving at the receivers (Nazarian and Stokoe, 1986b; Carino, 2004c). The phase differences are obtained by computing the **cross-power spectrum** of the signals recorded by the two receivers. The phase portion of the cross-power spectrum gives phase differences (in degrees) as a function of frequency. A schematic of such a phase spectrum is shown on the left side of Figure 21.18.* The phase velocities are determined as follows:

$$C_{R(f)} = X \frac{360}{\phi_f} f \quad (21.23)$$

where:

$C_{R(f)}$ = surface wave speed of component with frequency f .

X = distance between receivers (see Figure 21.17).

ϕ_f = phase angle of component with frequency f (degrees).

The wavelength (λ_f) corresponding to a component frequency is calculated using the following relationship:

$$\lambda_f = X \frac{360}{\phi_f} \quad (21.24)$$

By repeating the calculations given by Equation 21.23 and Equation 21.24 for each component frequency, one obtains a plot of wavelength vs. phase velocity. Such a plot is called a **dispersion curve** and is shown on the right side of Figure 21.18.

* A phase spectrum is usually plotted so the phase angle axis ranges from -180° to 180° ; hence, the spectrum folds over when the phase angle reaches -180° , giving the phase spectrum a sawtooth pattern.

FIGURE 21.18 Schematic of phase spectrum (left) obtained from cross-power spectrum of the receiver waveforms in SASW testing and the dispersion curve (right) relating wavelength and wave speed.

After the experimental dispersion curve is obtained, a process called *inversion* is used to obtain the stiffness profile at the test site (Krstulovic-Opara et al., 1996; Nazarian and Desai, 1993; Nazarian and Stokoe, 1986b; Yuan and Nazarian, 1993). The site is modeled as layers of varying thickness. Each layer is assigned a density and elastic constants (shear modulus and Poisson's ratio). Using these assumed properties, the surface motion at the location of the receivers is calculated using numerical simulation of surface-wave propagation. The calculated responses are subjected to the same signal-processing technique as that used for the test data, and a theoretical dispersion curve is obtained. The theoretical and experimental dispersion curves are compared. If the curves match, the problem is solved, and the assumed stiffness profile is correct. If significant discrepancies are found, the properties of the assumed layered system are changed, and a new theoretical dispersion curve is calculated. This process is repeated until there is agreement between the theoretical and experimental dispersion curves. The user should be experienced in selecting plausible starting values of the elastic constants and should be able to recognize whether the final values are reasonable. Convergence cannot be assumed to indicate that the correct values have been determined, because it is possible for different combinations of layer thicknesses and elastic moduli to result in similar dispersion curves.

The general configuration for SASW testing was shown in Figure 21.17. For reliable results, tests are repeated with different receiver spacings (Nazarian and Stokoe, 1986a). The receivers are first located close together, and the spacing is increased by a factor of two for subsequent tests. As a check on the measured phase information for each receiver spacing, a second series of tests is carried out by reversing the position of the source. Typically, five receiver spacings are used at each test site. For tests of concrete pavements, the closest spacing is usually about 150 mm. The SASW method has been used to determine the stiffness profiles of soil sites and of flexible and rigid pavement systems (Nazarian and Stokoe, 1986b; Rix and Stokoe, 1989), and the method has been extended to the measurement of changes in the elastic properties of concrete slabs during curing (Rix et al., 1990).

21.3.3.4 Summary

The impact techniques discussed in this section offer great potential as reliable methods for flaw detection. Although they appear similar in terms of the physical test procedure, different information about the test object can be obtained by using the correct instrumentation and signal-processing methods. Each method is best suited for particular applications. Persons interested in using NDT methods based on stress-wave propagation should develop the ability to use all the methods, so the most appropriate one can be used for a particular situation.

21.3.4 Infrared Thermography

Infrared thermography is a technique for locating near-surface defects by measuring surface temperature. It is based on two principles. The first principle is that a surface emits electromagnetic radiation with an intensity that depends on its temperature; at about room temperature, the radiation is in the infrared

region of the electromagnetic spectrum. The second principle is that the presence of an anomaly having a lower thermal conductivity than the surrounding material will interfere with the flow of heat and alter the surface-temperature distribution. As a result, the surface temperature will not be uniform; thus, by measuring the surface temperature at different points, the presence of the defect can be inferred. In practice, the surface temperature is measured with an infrared scanner that works in a manner similar to a video camera (Manning and Holt, 1980). The output of the scanner is a **thermographic image** of temperature differences.

The following are values of thermal-conductivity for different materials (Halliday and Resnik, 1978):

Material	Thermal Conductivity (J/s·m·°C)
Steel	46
Ice	1.7
Concrete	0.8
Air	0.024

It can be seen that air has a much lower thermal conductivity than concrete, and this explains why the presence of air voids within concrete can affect the surface-temperature distribution when there is heat flow through concrete.

In civil-engineering applications, infrared thermography has been used primarily to detect corrosion-induced delaminations in reinforced-concrete bridge decks. In North America, early research on this application was performed independently in the late 1970s by the Virginia Highway and Transportation Research Council (Clemeña and McKeel, 1978) and by the Ontario Ministry of Transportation and Communication (Manning and Holt, 1983). Initial studies involved hand-held scanners and photographic cameras to record the thermographic images. This was followed by scanning from a boom attached to a truck and by airborne scanning using a helicopter. Although infrared thermography allowed more rapid surveys than the chain-drag technique (ASTM D 4580) (ASTM, 2003a), it was not as accurate as chain dragging for determining the extent of delaminations (Manning and Holt, 1983). In 1988, ASTM published a standard test method (ASTM D 4788) (ASTM, 2003b) on the use of infrared thermography to locate delaminations in exposed and overlaid concrete bridge decks. Additional information on considerations for performing an infrared survey and representative case histories are provided by Weil (2004).

The principle of infrared thermography is illustrated in Figure 21.19. The presence of a void in the concrete slab has a local insulating effect that disrupts the heat flow through the slab and affects the surface temperature. When heat flows into the slab, the area above the void is warmer than the surrounding area, and when heat flows out of the slab, the area above the void is cooler. By measuring the surface temperature distribution, one can infer the presence of the void; hence, the application of infrared thermography requires a heat-flow condition through the test object and a means for measuring small differences in surface temperature. The required heat-flow condition can be created artificially by using heating lamps, or it can occur naturally through solar heating (heat flow into the structure) and nighttime cooling (heat flow out of the structure). The latter approach is obviously more economical. The best time for doing infrared surveys is 2 to 3 hours after sunrise or after sunset (Weil, 2004). Heat flow decreases and surface temperatures become uniform with time after sunrise or sunset.

Even with the proper heat-flow conditions, not all delaminations are detectable. Maser and Roddis (1990) performed analytical studies to gain an understanding of the factors affecting the differences in the surface temperature of a solid concrete slab and a slab with a delamination. It was found that the maximum differential surface temperature decreased as the depth of the delamination increased and as the width decreased. Also, a water-filled delamination resulted in nearly identical surface temperatures as a solid slab.

In infrared thermography, differences in surface temperature are measured by using an imaging infrared scanner, a device similar to a video camera which measures the amount of infrared radiation emitted by a surface. As mentioned, the underlying principle of this measurement method is that an object at a temperature above absolute zero emits electromagnetic radiation, the wavelength of which depends on the temperature. As the temperature increases, wavelengths become shorter, and, at a sufficiently high

FIGURE 21.19 Effect of a void on the heat flow through a concrete slab.

temperature, the radiation is in the visible spectrum. This is the operating principle of incandescent light bulbs. At room temperature range, the wavelength of the radiation emitted by surfaces is on the order of $10\text{ }\mu\text{m}$, which is in the infrared region of the spectrum. This radiation cannot be detected by the naked eye. The infrared scanner has a detector that senses the infrared radiation. The detector output is related to the amount of incident radiant energy.

The energy emitted by a surface is related to its temperature according to the Stefan–Boltzman law (Halliday and Resnik, 1978):

$$R = e\sigma T^4 \quad (21.25)$$

where:

R = rate of energy radiation per unit area of surface (W/m^2).

e = emissivity of the surface.

σ = Stefan–Boltzman constant, $5.67 \times 10^{-8}\text{ W}/(\text{m}^2 \cdot \text{K}^4)$.

T = absolute temperature of the surface (degrees Kelvin).

With calibration, the output from the infrared sensor can be converted to a temperature. The emissivity is characteristic of the material and surface texture and has a value ranging from 0 to 1. Because the rate of energy radiation depends on temperature and emissivity, care must be exercised in interpreting thermographic images to ensure that apparent temperature differences are not caused by differences in emissivity. The emissivity of bridge deck surfaces can be affected by the type of texturing, oil spots, tire marks, paint, and loose debris.

Equipment for performing a thermographic survey includes an infrared scanner with associated hardware capable of producing a video image of the temperature distribution of the scanned surface; a conventional video camera to provide a visual record for comparison with the infrared record; video recorders to record infrared and conventional video images; analog-to-digital converters to transform the video images into digital data; a computer system and software for data storage and signal enhancement; and a distance-referencing system to correlate the infrared scan with position on the bridge deck (Kunz and Eales, 1985; Weil, 2004). The equipment is contained typically in a mobile van that travels along the roadway while data are recorded. The resolution of some infrared scanners is improved by lowering the temperature; therefore, a liquid nitrogen cooling system is used to cool the sensors. Modern infrared thermography systems do not require such cooling, making them simpler to use. Available equipment allows resolution of differences in surface temperature as low as 0.1°C .

The following is a summary of the procedure given in ASTM D 4788 for performing an infrared thermographic survey to detect delaminations in bridge decks:

- Remove debris from the surface.
- Allow the surface to dry for at least 24 hr before testing.
- Be sure there is at least a 0.5°C difference between the surface temperatures in areas above delaminations and in sound concrete. At least 3 hr of direct sunlight are generally sufficient to establish this temperature difference. A contact thermometer with a resolution of at least 0.1°C is used to determine whether the minimum temperature difference has been established.
- Do not test when the wind speed exceeds 50 km/hr because the surface temperature will be affected.
- Do not test when the ambient air temperature is less than 0°C because ice in delaminations will give false indications of sound concrete. As a guide, an ambient temperature rise of 10°C, 4 hr of sunshine, and a wind speed below 25 km/hr should result in accurate data on bare concrete surfaces during winter. For asphalt-covered concrete, at least 6 hr of sunshine are necessary during winter.
- Collect data with the van moving at speeds not greater than 15 km/hr.

The results of the inspection are usually reported in terms of delaminated area and percentage of total area that is delaminated. After the delaminated areas are identified in the infrared images, the visible video images should be compared to ensure that apparent temperature differences were not due to emissivity changes (Kunz and Eales, 1985). The ASTM standard states that 80 to 90% of the delaminations in a bare bridge deck can be located with this method. It has also been found that inspection of the same deck by four different operators resulted in a variation of $\pm 5\%$ of the known delaminated area.

A more recent development has been the use of infrared thermography to evaluate structural repairs made using bonded fiber-reinforced polymer (FRP) sheets. These repairs are made by bonding laminates of fiber cloth on the outside of a member. After the adhesive has cured, the FRP acts as external reinforcement. It is important to achieve good bonding with the concrete substrate and between the plies of FRP. It has been shown that active infrared thermography, in which heating lamps are used to create a transient heat-flow condition, is effective in locating voids that may exist between FRP plies or at the FRP-concrete interface (Levar and Hamilton, 2003; Starnes and Carino, 2003; Starnes et al., 2003).

In summary, instrumentation and computer software have been developed so inspection of bridge decks by infrared thermography is a fairly routine procedure (Kunz and Eales, 1985). Trained individuals are required to ensure that meaningful data are collected and that data are correctly interpreted. Infrared thermography is a **global** inspection method that permits large surface areas to be scanned in a short period of time, which is an advantage over other point-by-point methods that have been discussed.

21.3.5 Ground-Penetrating Radar

Radar is analogous to the ultrasonic pulse-echo technique previously discussed, except that pulses of electromagnetic waves (short radiowaves or microwaves) are used instead of stress waves. Early uses of the technique were for military applications, but radar techniques are now used in a variety of fields, such as weather, aerial mapping, and civil-engineering applications. The earliest civil-engineering applications for radar were probing into soil to detect buried pipelines and tanks. This was followed by studies to detect cavities below airfield pavements and more recently for determining concrete thickness, locating voids and reinforcing bars, and identifying deterioration (Alongi et al., 1982; Bungey and Millard, 1993; Cantor, 1984; Cantor and Kneeter, 1982; Carter et al., 1986; Clemeña, 1983; Kunz and Eales, 1985; Maser, 1986; Maser and Roddis, 1990; Steinway et al., 1981; Ulriksen, 1983). Clemeña (2004) provides a review of the applications of radar to concrete.

In civil-engineering applications, relatively short distances are involved compared with other uses of radar; thus, devices for these applications emit very short pulses of electromagnetic waves (microwaves). For this reason, the technique is often called *short-pulse radar* or *impulse radar*. Others refer to it as *ground-penetrating radar* (GPR), which is the term used in this chapter. This section discusses the principles of GPR, the instrumentation that is used, and some of the inherent difficulties in using the method.

FIGURE 21.20 Reflection of electromagnetic pulse at interfaces between materials with different relative dielectric constants and antenna signal (right) caused by arrival of echoes.

Propagation of electromagnetic waves is a complex phenomenon. The following presentation is simplified based on assumptions suitable for civil-engineering applications. More detailed treatments are available (Daniels et al., 1988; Halabe et al., 1993, 1995). The operating principle of GPR is illustrated in Figure 21.20. An antenna above the test object sends out a short-duration pulse (on the order of nanoseconds) of electromagnetic waves. Some of the energy in the pulse travels through the test object, and when the pulse encounters an interface between dissimilar materials a fraction of the energy is reflected back toward the antenna as an *echo*. The antenna receives the echo and generates an output signal, as shown to the right in Figure 21.20. By measuring the time from the start of the pulse until the reception of the echo, one can determine the depth of the interface if the propagation speed through the material is known. This time-domain approach is analogous to the seismic-echo method based on stress-wave propagation.

The fraction of the incident pulse that is reflected at an interface depends on the difference between the relative dielectric constants* of the two materials and is given by the following equation (Bungey and Millard, 1993; Clemená, 2004):

$$\rho_{1,2} = \frac{\sqrt{\epsilon_{r1}} - \sqrt{\epsilon_{r2}}}{\sqrt{\epsilon_{r1}} + \sqrt{\epsilon_{r2}}} \quad (21.26)$$

where:

- $\rho_{1,2}$ = reflection coefficient.
- ϵ_{r1} = relative dielectric constant of material 1.
- ϵ_{r2} = relative dielectric constant of material 2.

Note the similarity of Equation 21.26 to Equation 21.20 for reflection of stress waves.

* The relative dielectric constant is related to the alignment of charges that occurs in an insulating material when placed in an electric field.

By definition, the relative dielectric constant of air equals 1, and typical values from ASTM D 4748 (ASTM, 2006a) for other materials are as follows:

Material	Range of Relative Dielectric Constant
Portland cement concrete	6 to 11
Asphalt–cement concrete	3 to 5
Gravel	5 to 9
Sand	2 to 6
Rock	6 to 12
Water	8

The relative dielectric constants for materials such as concrete and soil depend on the moisture content and ionic concentrations (Morey, 1974). Note that the dielectric constant of water is much higher than the other listed materials. This makes water the most significant dielectric contributor to construction materials and explains why radar is highly sensitive to moisture. As the moisture content increases, the dielectric constant of the material, such as concrete, also increases. Equation 21.26 shows that when the value of ϵ_r of material 2 is greater than that of material 1, the reflection coefficient is negative. This signifies a phase reversal in the reflected wave, which means that the positive part of the wave is reflected as a negative part. At a metal interface, such as between concrete and steel reinforcement, there is complete reflection and the reflected wave has reversed polarity. This makes GPR very effective for locating metallic embedments. On the other hand, strong reflections from embedded metals can obscure weaker reflections from other reflecting interfaces that may be present, and reflections from reinforcing bars may mask reflections from greater depths.

An important difference between GPR and stress-wave methods, such as the impact-echo method, is the amplitude of the reflections at a concrete–air interface. For stress waves, the reflection is almost 100% because the acoustic impedance of air is negligible compared with concrete. On the other hand, the mismatch in dielectric constants at a concrete–air interface is not as drastic, and only about 50% of the incident energy is reflected at a concrete–air interface. This results in two significant differences between GPR and stress-wave methods. GPR is not as sensitive to the detection of concrete–air interfaces as are stress-wave methods; however, because not all the energy is reflected at a concrete–air interface, GPR is able to penetrate beyond such an interface and detect features below the interface.

The depth of the reflecting interface is obtained from the measured round-trip travel time and the speed of the electromagnetic wave (C), which depends on the relative dielectric constant:

$$C = \frac{C_0}{\sqrt{\epsilon_r}} \quad (21.27)$$

where:

C_0 = speed of light in air (3×10^8 m/s).

ϵ_r = relative dielectric constant.

If the round trip travel time is Δt , then depth D would be:

$$D = C \frac{\Delta t}{2} \quad (21.28)$$

Equation 21.26 through Equation 21.28 form the basis for using GPR to inspect concrete structures.

Typical instrumentation for GPR includes the following main components: an antenna unit, a control unit, a display device, and a storage device. The antenna emits the electromagnetic pulse and receives the echoes. The length of the pulse is largely controlled by the antenna design. Longer pulses are associated with longer wavelengths (or lower frequency) and have greater penetrating ability but poorer resolution (poorer ability to detect small objects) than shorter pulses. Typically, an antenna with a predominant

FIGURE 21.21 Waterfall plot of radar waveforms as an antenna is scanned across the surface of the test object. (Adapted from Cantor, T.R., in *In Situ/Nondestructive Testing of Concrete*, Malhotra, V.M., Ed., ACI SP-82, American Concrete Institute, Farmington Hills, MI, 1984, pp. 581–601.)

frequency of about 1 GHz is used to inspect pavements and bridge decks, and the pulse length is about 1 ns. In air, such a pulse is about 0.3 m long, and in concrete the length would depend on the value of ϵ_r . For $\epsilon_r = 6$, the pulse length would be about 120 mm. To be able to measure depths accurately, the echo must arrive after the initial pulse has ceased; therefore the round-trip travel path must exceed the pulse length. For $\epsilon_r = 6$, the minimum depth that can be measured accurately is about 60 mm. As ϵ_r increases, the minimum measurable depth decreases.

The pulse is attenuated as it travels through the test object, and there is a limit to the thickness that can be inspected. For concrete, the depth of penetration would depend on the characteristics of the GPR system, the moisture content, and the amount of reinforcement. With increasing moisture content and amount of reinforcement, penetration decreases. For dry unreinforced concrete, the maximum penetration of the pulse produced by a 1-GHz antenna is about 0.6 m (Clemeña, 2004). Figure 21.20 shows a horn antenna that is not in direct contact with the test object. In this case, the received signal includes an echo from the concrete surface. It is also possible to use a contact, or ground-coupled, dipole antenna that rests directly on the testing surface. In this case, the pulse emitted by the transmitting part of the antenna is picked up immediately by the receiving part.

The control unit is the heart of a GPR system. It controls the repetition frequency of the pulse, provides the power to emit the pulse, acquires and amplifies the received signal, and provides output to a display device. Data are usually stored and played back for later analysis and signal interpretation.

Older types of display devices include oscillographs, which plot the recorded waveforms as a **waterfall plot**, or graphic-facsimile recorders, which provide a cross-sectional view of the test object. As an example, Figure 21.21 shows a waterfall plot obtained by plotting the received waveforms next to each other. The plot takes on a topographic appearance, and changes in the pattern of the received signals are relatively easy to identify (Cantor, 1984). Computer software is also available that permits sophisticated signal processing of the data to aid in interpretation.

The operation of the graphic recorder is discussed further here because it was commonly used in the field and the same principles are applicable to modern computer displays. Figure 21.22a shows a ground-coupled, dipole antenna emitting a radar pulse into a test object containing a void. The shape of the emitted pulse is sketched above the antenna. Figure 21.22b shows the waveform from the receiving side of the antenna. The vertical axis represents time, or it can be transformed to depth by knowing ϵ_r and using Equation 21.28. The received signal at the start of the waveform represents the transmitted pulse, which is picked up directly by the receiving side of the antenna. The second received signal is the echo from the void, and the third is the echo from the bottom boundary of the test object.

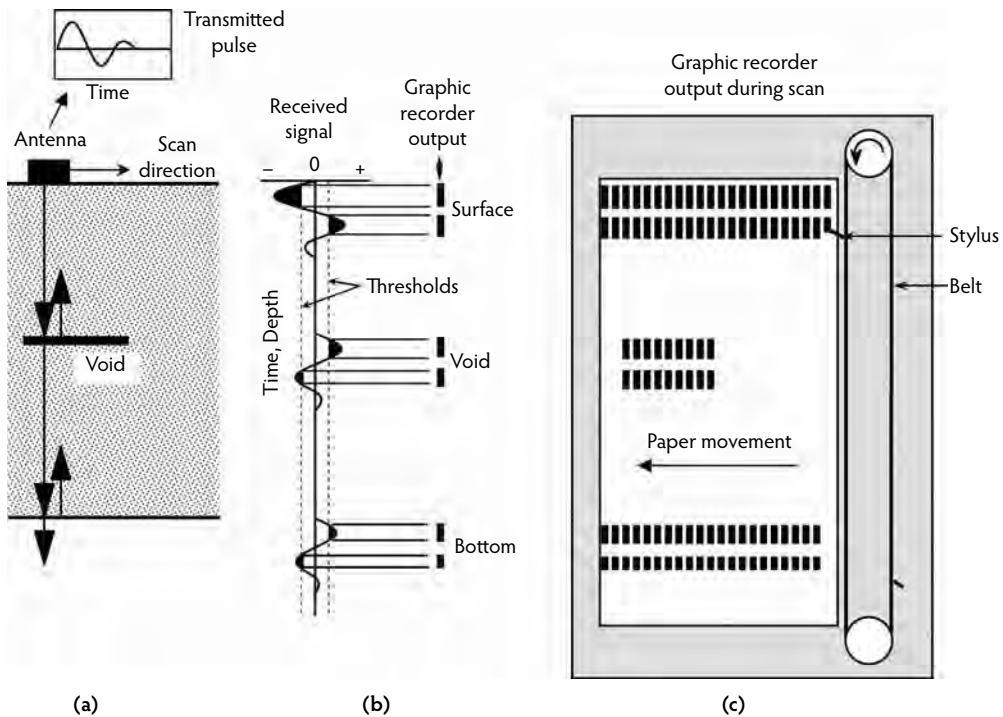

FIGURE 21.22 Schematic to illustrate peak-plotting technique used with graphic recorder: (a) reflections of electromagnetic pulse in test object; (b) received waveform and threshold limits; (c) graphic recorder output during surface scan of test object.

The output displayed by the graphic recorder is obtained by a technique known as *peak plotting*, which is illustrated in Figure 21.22b. First, the operator selects a threshold voltage range. When the amplitude of the received signal goes beyond the threshold range, the pen of the graphic recorder plots a solid line on recording paper. The line is plotted in varying shades of gray, depending on the amplitude of the signal. Thus, the antenna output is represented on the graphic recorder as a series of dashes, as shown in Figure 21.22b. Note that each echo is associated with two dashes. The actual number of dashes depends on the number of cycles in the emitted pulse and the threshold level. This is an important point to understand for proper interpretation of GPR results. As the antenna is moved along the surface, the output is displayed on the graphic recorder. The paper on the recorder moves at a constant speed that is independent of the speed of the antenna motion. The resulting display on the graphic recorder represents a cross-sectional view of the test object, as illustrated in Figure 21.22c. The test equipment provides a means for correlating the position of the antenna during the scan with the location on the paper record or computer display, so it is possible to determine the depth and approximate length (along the scan direction) of the reflecting interface.

As was mentioned, metals are strong reflectors of electromagnetic waves. This makes GPR very effective for locating buried metal objects such as reinforcing bars and conduit. Reinforcing bars result in characteristic patterns in the graphic-recorder output, which make them relatively easy to locate. There are two main factors leading to these patterns, which are discussed here with the aid of Figure 21.23. First of all, an antenna behaves like a flashlight in that the beam of radiation has a conical shape, so a reinforcing bar produces echoes before the antenna passes directly over the bar; however, the apparent depth of the bar will be larger than the actual cover because of the longer inclined travel path. Second, the pulse undergoes multiple reflections, or reverberations, between the reinforcing bar and the surface, and the output will show multiple echoes from the same bar. The resulting characteristic pattern is shown on the right side of Figure 21.23. The top of the bar is associated with the uppermost part of the arched bands.

FIGURE 21.23 Schematic to illustrate characteristic pattern from ground-penetrating radar (GPR) scan over a reinforcing bar.

When multiple reinforcing bars are present, multiple arch patterns will be obtained. As the distance between bars decreases, the arch patterns overlap. At less than a critical spacing, the individual bars can no longer be discerned, and the echo pattern is similar to the case of a solid embedded steel plate. The ability to discern individual bars depends on bar size, bar spacing, cover depth, and configuration of the antenna (Bungey et al., 1994). Closely spaced bars will also prevent detection of features below the layer of reinforcement. This masking effect depends on the wavelength of the electromagnetic waves, the bar size, and cover depth. It has been found that for the 1-GHz, hand-held antenna, 32-mm-diameter bars at cover depths of 25 to 50 mm will prevent detection of underlying features when bar spacing is less than 200 mm (Bungey et al., 1994).

Simple methods do not exist to determine bar size from GPR output. Researchers have attempted to better understand the interactions of GPR with cracks, voids, and reinforcing bars (Mast et al., 1990). The objective of these studies is to develop procedures to use the recorded data to construct an image of the interior of the concrete. Some advances in this direction have occurred in France, where a prototype system has been developed that uses tomographic techniques to reconstruct the two-dimensional layout of reinforcement in concrete (Pichot and Trouillet, 1990). In the United States, successful three-dimensional reconstruction of artificial defects and reinforcement embedded in a concrete slab has been demonstrated (Mast and Johansson, 1994). These imaging methods rely on an antenna array to make multiple measurements and require extensive computational time to reconstruct the internal image.

The detection of delaminations in reinforced bridge decks using GPR is not straightforward. In studies by Maser and Roddis (1990), it was found that a 3-mm air gap in concrete produced little noticeable effect in the received waveform, but the addition of moisture to the simulated crack resulted in stronger reflections that were noticeable in the waveform. It was also found that the presence of chlorides in moist concrete resulted in high attenuation because of the increased conductivity. Thus, the ability to detect delaminations will depend on the *in situ* conditions at the time of testing. In addition, the reflections from reinforcing bars are much stronger than from a delamination, making it difficult to detect the delamination.

Within ASTM, two standards have been developed on the use of GPR in highway applications. Test Method D 4748 (ASTM, 2006a) can be used to measure the thickness of the upper layer of a multilayer pavement system. Basically, the technique involves measuring the transit time of the pulse through the pavement layer and using relationships similar to Equation 21.27 and Equation 21.28 to calculate the layer thickness. The procedure is based on using a non-contact horn antenna, so some modifications are required for measurements with a contact antenna. The calculated depth depends on the value of the relative dielectric constant. Errors in the assumed value of the relative dielectric constant can lead to

substantial inaccuracies in depth estimations (Bungey et al., 1994). For data obtained with a horn antenna, the relative dielectric constant of the concrete can be computed directly from the radar signals. For data obtained using a contact antenna, it is necessary to take occasional cores to determine the appropriate value for the pavement materials. The user is cautioned against using the method on saturated concrete because of the high attenuation and limited penetration of the pulse. In ASTM D 4748, it is stated that interoperator testing of the same materials resulted in thickness measurements within ± 5 mm of the actual thickness. Finally, it is noted that reliable interpretation of received signals can only be performed by an experienced data analyst. Test Method D 6087 (ASTM, 2007b) was originally developed in 1997 to provide a standard procedure for using GPR to evaluate the presence of delaminations due to corrosion of the top layer of reinforcement in concrete bridge decks.

Although the majority of GPR applications have dealt with locating reinforcing bars in structures, locating delaminations in bridge decks, and measuring the thickness of pavement layers, there are other potential uses. Because the dielectric properties of a material such as concrete depend strongly on the moisture content, microwave measurements can be used to monitor the progress of hydration (Clemeña, 2004; Otto et al., 1990). This is made possible because the relative dielectric constant of free water is much higher than that of chemically bound water. Clemeña (2004) has also reported on potential applications of microwave measurements to determine water content of fresh concrete. In addition, microwave sensors are used in ready-mixed concrete plants to measure the moisture content of aggregates stored in bins.

21.3.6 Electrical and Magnetic Methods for Reinforcement

Information about the quantity, location, and condition of reinforcement is needed to evaluate the strength of reinforced concrete members. This section discusses some of the magnetic and electrical methods that are used to gain information about embedded-steel reinforcement. Additional information may be found in ACI 228.2R (ACI Committee 228, 1998), Bungey and Millard (1996), Carino (2004d), Lauer (2004), and Malhotra (1976).

21.3.6.1 Covermeters

Devices to locate reinforcing bars and estimate the diameter and depth of cover are known as *covermeters*. These devices are based on interactions between the bars and low-frequency electromagnetic fields. The physical principle that is employed is that of **electromagnetic induction**, whereby an alternating magnetic field induces an electrical potential in an electrical circuit intersected by the field. Commercial covermeters can be divided into two classes: those based on the principle of **magnetic reluctance** and those based on **eddy currents**. These differences are summarized below (Carino, 1992b).

21.3.6.2 Magnetic-Reluctance Meters

When current exists in an electrical coil, a magnetic field is created and magnetic flux lines are created between the magnetic poles. This leads to a magnetic circuit, in which the magnetic flux between poles is analogous to the current in an electrical circuit (Fitzgerald et al., 1967). The resistance to creation of magnetic flux is called *reluctance*, which is analogous to the resistance to flow of charge in an electrical circuit. Figure 21.24 provides a schematic of a covermeter that is based on changes in the reluctance of a magnetic circuit caused by the presence or absence of a steel bar within the vicinity of the search head. The search head is composed of a ferromagnetic U-shaped core (yoke), an excitation coil, and a sensing coil. When alternating current (less than 100 Hz) is applied to the excitation coil, an alternating magnetic field is created, and a magnetic flux is established between the poles of the yoke. In the absence of a bar (Figure 21.24a), the magnetic circuit, composed of the yoke and the concrete between the ends of the yoke, has high reluctance, and the alternating magnetic flux in the magnetic circuit will be small. The alternating flux induces a small, secondary current in the sensing coil. If a ferromagnetic bar is present (Figure 21.24b), the reluctance decreases, the magnetic flux amplitude increases, and the sensing-coil current increases. Thus, the presence of the bar is indicated by a change in the output from the sensing

FIGURE 21.24 Covermeter based on the principle of magnetic reluctance. (Adapted from Carino, N.J., *Performance of Electromagnetic Covermeters for Nondestructive Assessment of Steel Reinforcement*, NISTIR 4988, National Institute of Standards and Technology, Gaithersburg, MD, 1992.)

coil. For a given reinforcing bar, the reluctance of the magnetic circuit depends strongly on the distance between the bar and the poles of the yoke. An increase in concrete cover increases the reluctance and reduces the current in the sensing coil. If the meter output were plotted as a function of the cover, a relationship would be established that could be used to measure the cover. Because the size of the bar affects the reluctance of the magnetic circuit, there would be a separate relationship for each bar size.

21.3.6.3 Eddy-Current Meters

If a coil carrying an alternating current is brought near an electrical conductor, the changing magnetic field induces circulating currents in the conductor. These are known as *eddy currents*. Because any current gives rise to a magnetic field, eddy currents produce a secondary magnetic field that interacts with the field of the coil. The second class of covermeters is based on monitoring the effects of the eddy currents induced in a reinforcing bar. Figure 21.25 provides a schematic of a continuous eddy-current covermeter. In the absence of a reinforcing bar, the magnitude of the alternating current (usually at about 1 kHz) in the coil depends on the coil impedance.* If the coil is brought near a reinforcing bar, alternating eddy currents are established within the surface of the bar. The eddy currents give rise to an alternating

* When direct current is applied to a circuit, the current amplitude equals the voltage divided by the electrical resistance of the circuit. When alternating current is applied to a coil, the current amplitude is governed by the value of the applied voltage, the resistance, and another quantity called **inductance**. The vector sum of resistance and inductance defines the **impedance** of the coil.

Presence of reinforcing bar causes changes in coil impedance and current amplitude.

FIGURE 21.25 Covermeter based on eddy-current principle. (Adapted from Carino, N.J., *Performance of Electromagnetic Covermeters for Nondestructive Assessment of Steel Reinforcement*, NISTIR 4988, National Institute of Standards and Technology, Gaithersburg, MD, 1992.)

secondary magnetic field that induces a secondary current in the coil. In accordance with Lenz's law (Serway, 1983), the secondary current opposes the primary current. As a result, the net current flowing through the coil is reduced, and the apparent impedance of the coil increases (Hagemaijer, 1990); thus, the presence of the bar is inferred by monitoring the change in current flowing through the coil.

Covermeters based on continuous excitation are relatively inexpensive but are not stable. An improvement is provided by covermeters based on pulsed excitation, as illustrated in Figure 21.26. A repetitive current pulse is applied to the coils. There is a period of dead time between the end of one pulse and the start of the next pulse. Measurements to infer the presence of reinforcement are made during this dead time. When the pulse is applied, current increases gradually, but then the current is turned off rapidly. The sudden end of the pulse causes a sudden collapse in the magnetic field of the coils, which induces eddy currents in a bar located below the coils. As the eddy currents decay, a decaying magnetic field induces a secondary current in the coils. The amplitude of the induced current depends on the depth and size of the bar; thus, by measuring the amplitude of the induced current during the dead time, information about the bar can be inferred. Note that in this case the search head includes two coils, which make it directional—that is, the output is largest when the coils are aligned with the bar (Carino, 1992b).

21.3.6.4 Covermeter Characteristics

A reinforcing bar is detected by a covermeter when the bar lies within the **zone of influence** of the search head (yoke or coil). The response is maximum when the search head lies directly above the reinforcing bar. An important characteristic of a covermeter is the relationship between meter amplitude and the horizontal distance from the longitudinal axis of the bar to the axis of the search head. The variation has approximately the same shape as the bell-shaped curve of a normal probability distribution. The width of the curve defines the zone of influence of the search head. A search head with a smaller zone of

FIGURE 21.26 Covermeter based on pulsed-induction principle. (Adapted from Carino, N.J., *Performance of Electromagnetic Covermeters for Nondestructive Assessment of Steel Reinforcement*, NISTIR 4988, National Institute of Standards and Technology, Gaithersburg, MD, 1992.)

influence is better able to discern individual bars when they are closely spaced compared with a search head with a wider zone of influence, but focused search heads generally have less penetrating ability. The influence zone of the search head also affects the accuracy when trying to detect the end of a reinforcing bar (Carino, 1992b).

An important distinction between covermeters is the directionality characteristics of the search heads. Because of the shape of the yoke, a magnetic-reluctance meter is directional compared with a continuous eddy-current meter with a symmetrical coil. Maximum response occurs when the yoke is aligned with the axis of the bar. This directionality can be used to advantage when testing a structure with an orthogonal grid of reinforcing bars (Tam et al., 1977). As stated above, a pulsed excitation covermeter with two coils in the search head is also directional.

For a given covermeter, unique relationships exist between meter amplitude and depth of cover for different bar sizes. Figure 21.27 shows these relationships for a magnetic reluctance and for an eddy-current meter. These relationships illustrate a basic limitation of covermeters. Because the amplitude is a function of bar diameter and depth of cover, one cannot determine both parameters from a single measurement. As

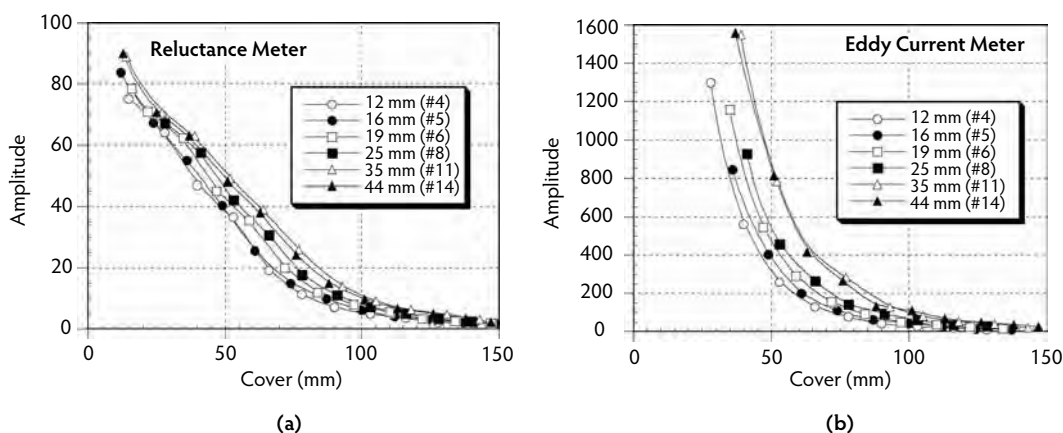

FIGURE 21.27 Amplitude vs. cover: (a) for a magnetic reluctance meter, and (b) for eddy-current meter. (Adapted from Carino, N.J., *Performance of Electromagnetic Covermeters for Nondestructive Assessment of Steel Reinforcement*, NISTIR 4988, National Institute of Standards and Technology, Gaithersburg, MD, 1992.)

a result, dual measurements are necessary to estimate both depth of cover and diameter (BSI, 1988; Das Gupta and Tam, 1983). This is done by first recording the meter amplitude with the search head in contact with the concrete and then recording the amplitude when the search head is located a known distance above the concrete. The difference in amplitudes and the amplitude–cover relationships are used to estimate the cover and bar diameter. The accuracy of this spacer technique depends on how distinct the amplitude–cover relationships are for the different bar sizes. Because these relationships are generally similar for adjacent bar sizes, it is generally only possible to estimate bar diameter within two sizes (Bungey and Millard, 1996).

The single-bar, amplitude–cover relationships are only valid when the bars are sufficiently far apart so there is little interference by adjacent bars. For multiple, closely spaced bars, the amplitude may exceed the amplitude for a single bar at the same cover depth. If they are closer than a critical amount, the individual bars cannot be discerned. The critical spacing depends on the type of covermeter and the cover depth. In general, as cover increases, the critical spacing also increases (Carino, 1992b). Because the response of a covermeter to the presence of multiple, closely spaced bars depends on its design, the user should follow the manufacturer's recommendations regarding minimum bar spacing.

The presence of two layers of reinforcement within the zone of influence cannot generally be identified with ordinary covermeters (Bungey and Millard, 1996; Carino, 1992b). The upper layer produces a much stronger signal than the deeper second layer so the presence of the second layer cannot be discerned. It has been shown, however, that it may be possible to determine lap length when bars are in contact (Carino, 1992b).

In summary, covermeters are effective for locating individual bars, provided that the spacing exceeds a critical value that depends on the meter design and the cover depth. By using multiple measurement methods, bar diameter can generally be estimated to within two adjacent bar sizes if the spacing exceeds certain limits that also depend on the particular meter. Meters are available that can estimate bar diameter without using spacers to make multiple measurements. Again, the accuracy of these estimates decreases as bar spacing decreases. To obtain reliable measurements, it is advisable to prepare mock-ups of the expected reinforcement configuration to establish whether the desired accuracy is feasible. These mock-ups can be made without using concrete (BSI, 1988; Carino, 1992b), provided the in-place concrete does not contain significant amounts of iron-bearing aggregates.

21.3.6.5 Corrosion Activity

Electrical methods are used to evaluate corrosion activity of steel reinforcement. As is the case with other NDT methods, an understanding of the underlying principles of these electrical methods is needed to obtain meaningful results. In addition, an understanding of the factors involved in the corrosion mechanism is essential for reliable interpretation of data. The subsequent sections provide basic information about these methods. Because of the complex interaction of factors, a corrosion specialist should be consulted when planning an investigation. Refer to Carino (2004d) for a more comprehensive review of methods to monitor corrosion activity.

Corrosion is an electrochemical process involving the flow of charges (electrons and ions). At active sites on the bar, called *anodes*, iron atoms lose electrons and move into the surrounding concrete as ferrous ions. This process is referred to as a *half-cell oxidation reaction*, or the *anodic reaction*, and is represented as follows:

The electrons remain in the bar and flow to sites, called *cathodes*, where they combine with water and oxygen that are present in the concrete. The reaction at the cathode is the *half-cell reduction reaction* and is represented as follows:

To maintain electrical neutrality, the ferrous ions migrate through the concrete to these cathodic sites, where they combine with water and oxygen to form hydrated iron oxide, or rust; thus, when the bar is

FIGURE 21.28 Apparatus for half-cell potential method described in ASTM C 876.

corroding, electrons are flowing through the bar and ions are flowing through the concrete. When the bar is not corroding, there is no flow of electrons and ions. As the ferrous ions move into the surrounding concrete, the electrons that are left behind in the bar give the bar a negative charge and lead to an electric potential field in the concrete. The **half-cell potential method** is used to measure this potential field and thereby provide an indication of corrosion activity.

21.3.6.6 Half-Cell Potential Method

Figure 21.28 provides a schematic of the half-cell potential apparatus given in ASTM C 876 (ASTM, 1991), which includes a copper–copper-sulfate half cell,* connecting wires, and a high-impedance voltmeter. The positive terminal of the voltmeter is attached to the reinforcement, and the negative terminal is attached to the copper–copper-sulfate half cell. A high-impedance voltmeter is used so very little current exists in the circuit. The half cell makes electrical contact with the concrete by means of a porous plug and a sponge that is moistened with a wetting solution (such as liquid detergent).

If the bar is corroding, electrons would tend to flow from the bar to the half cell. At the half cell, the electrons are consumed in a reduction reaction that transforms copper ions in the copper-sulfate solution into copper atoms deposited on the rod. Because of the way the terminals of the voltmeter are connected, the voltmeter would indicate a negative value. The more negative the voltage reading, the higher the likelihood that the bar is corroding. The half-cell potential is also called the *corrosion potential*, and it is an open-circuit potential because it is measured under the condition of no current in the measuring circuit (ASTM, 2007a).

The half-cell potential readings are indicative of the probability of corrosion activity of reinforcement located beneath the reference half cell; however, this is true only if all of the reinforcement is electrically connected. To ensure that this condition exists, electrical resistance measurements between widely separated reinforcing bars should be carried out (ASTM, 1991). This means that access to the reinforcement has to be provided. The method cannot be applied to concrete with epoxy-coated reinforcement.

*This half-cell is composed of a copper bar immersed in a saturated copper-sulfate solution. It is one of many half cells that can be used as a reference to measure the electrical potential of embedded bars. The measured voltage depends on the type of half cell, and conversion factors are available to convert readings obtained with other reference cells to an equivalent readings for a copper–copper-sulfate half cell.

A key aspect of the test is ensuring that the concrete is sufficiently moist. If the measured potential at a test point does not change by more than ± 20 mV within a 5-minute period (ASTM, 1991), then the concrete is sufficiently moist. If this condition is not satisfied, the concrete surface must be wetted. According to ASTM C 876, two techniques can be used to evaluate the results: (1) the **numeric** technique, or (2) the **potential-difference** technique. In the numeric technique, the value of the potential is used as an indicator of the likelihood of corrosion activity. If the potential is more positive than -200 mV, there is a high likelihood that no corrosion is occurring at the time of the measurement. If the potential is more negative than -350 mV, there is a high likelihood that active corrosion is present. Corrosion activity is uncertain when the voltage is in the range of -200 to -350 mV. ASTM C 876 also states that, unless there is positive evidence to suggest their applicability, these numeric criteria should not be used under the following conditions:

- When carbonation extends to the level of the reinforcement
- When evaluating indoor concrete that has not been subjected to frequent wetting
- When comparing corrosion activity in outdoor concrete with highly variable moisture or oxygen content
- When formulating conclusions about changes in corrosion activity due to repairs that changed the moisture or oxygen content at the level of the steel

In the potential-difference technique, areas of active corrosion are identified on the basis of half-cell potential gradients. An equipotential contour map is created by plotting the test locations on a scaled plan view of the test area. The half-cell voltage readings at each test point are marked on the plan, and contours of equal voltage values are determined. Regions of corrosion activity are indicated by closely spaced contours or large potential gradients.

As has been stated, valid potential readings are possible only if the concrete is sufficiently moist, and the user must understand how to recognize when there is insufficient moisture. Because of the factors involved in corrosion testing, a corrosion specialist is recommended to properly interpret half-cell potential surveys under the following conditions (ASTM, 1991):

- The concrete is saturated with water.
- The concrete is carbonated to the depth of the reinforcement.
- The steel is coated (galvanized).

In addition, potential surveys should be supplemented with tests for carbonation and water-soluble chloride content. A major limitation of the half-cell potential method is that *it does not measure the rate of corrosion*. It only provides an indication of the **likelihood** of corrosion activity at the time the measurement is made.

21.3.6.7 Concrete Resistivity

The corrosion rate of reinforcement depends on the availability of oxygen for the cathodic reaction. It also depends on the electrical resistance of the concrete, which controls the ease with which ions can move through the concrete in the presence of a potential field. The electrical resistance of concrete depends on the microstructure of the paste and the moisture content of the concrete; thus, a useful test in conjunction with a half-cell potential survey is the measurement of the resistivity of the concrete.

The resistivity of a material is numerically equal to the electrical resistance of a unit cube of the material and has units of resistance (in ohms) times length (Millard et al., 1989). The resistance (R) of a conductor of area A and length L is related to the resistivity (ρ) as follows:

$$R = \rho \frac{L}{A} \quad (21.31)$$

No ASTM test method has been proposed for measuring the in-place resistivity of concrete; however, one technique that has been used successfully is shown in Figure 21.29 (Bungey and Millard, 1996). This

FIGURE 21.29 Four-probe, Wenner method to measure concrete resistivity.

approach is based on the classical four-electrode technique described by Wenner in 1915 which has been incorporated into ASTM G 57, a standard test method for measuring soil resistivity (ASTM, 2006b). The four equally spaced electrodes are electrically connected to the concrete surface. The outer electrodes are connected to a source of alternating current, and the inner electrodes are connected to a voltmeter. The “apparent” resistivity is given by the following expression (Wenner, 1915):

$$\rho = \frac{2\pi s V}{I} \quad (21.32)$$

where:

- s = electrode spacing.
- V = measured voltage.
- I = measured current.

The word *apparent* is used because Wenner derived Equation 21.32 under the assumption that the material is semi-infinite and homogeneous; thus, the relationship gives the correct measure of resistivity when these assumptions are satisfied. Deviations from Wenner’s assumptions lead to differences between the calculated apparent resistivity and the true resistivity of the material (Millard et al., 1990). Experimental and analytical studies have been carried out to establish the magnitudes of the errors between the apparent and true resistivity when Equation 21.32 is applied to a finite-sized concrete member (Millard et al., 1990). An important variable is the minimum electrode spacing that can be used. Because concrete is made of paste and aggregates, which have different resistivities, the spacing should be large enough so a representative average resistivity of the concrete is measured. The spacing determines the depth of the material that affects the measurements. The greater the spacing, the greater is the depth of concrete that contributes to the measurements. If the member is too shallow relative to the electrode spacing, boundary effects occur and Equation 21.32 is not a good approximation.

Based on their work, Millard et al. (1990) suggested that an electrode spacing of 50 mm is sufficient for typical concrete mixtures, and the width and depth of the member should be at least four times the electrode spacing. In addition, the edge distance should not be less than twice the electrode spacing. When these minimum dimensions are not satisfied, the apparent resistivity calculated by Equation 21.32 will exceed the true resistivity. Other factors that affect the calculated resistivity are the presence of a thin surface layer of low-resistivity concrete and the presence of reinforcing bars. Both of these conditions will result in an apparent resistivity that is lower than the true value at the level of the reinforcement. The effect of reinforcing bars is related strongly to the depth of cover and less so to the bar diameter (Millard et al., 1990). If possible, resistivity measurements should be conducted midway between two bars. When depth of cover is low and bar spacing is small, it may be possible to apply a correction factor if the diameter and location of the reinforcement are known (Millard et al., 1990).

Another technique for measuring resistivity is incorporated into one of the linear polarization devices to be described in the next section (Broomfield, 1996). In this case, the resistance measurement is affected by the concrete between the reinforcing bar and the point on the surface where a special probe is located. The author is not aware of comparisons of resistivities measured by the four-electrode device, and this single-probe device.

As noted by Carino (2004d), recommendations have been provided for relating values of concrete resistivity to the risk of corrosion (Bungey and Millard, 1996; Feliú et al., 1996). These recommended values are, however, not the same, which emphasizes the need for a better understanding of the relationship between concrete resistivity and corrosion risk when reinforcement loses its passivity.

In summary, concrete resistivity provides additional information to assist in assessing the likelihood of different levels of corrosion activity. It serves as a useful supplement to a half-cell potential survey. A high resistivity indicates that, even if the potential survey shows a high likelihood of active corrosion, the corrosion rate may be low. The resistivity of concrete is related to the ease with which ions can migrate through the concrete under the action of the potential field surrounding anodes and cathodes. The resistivity increases as the capillary pore space in the paste is reduced. This explains why concrete with low capillary porosity is vital for long service life under corrosion-inducing conditions.

21.3.6.8 Linear Polarization

The limitations of the half-cell potential method led to the development of several techniques to measure the rate of corrosion (Rodríguez et al., 1994). This section provides an overview of the **linear polarization method**, the approach used most frequently in the field (Cady and Gannon, 1992; Flis et al., 1992).

In the field of corrosion science, the term *polarization* refers to the change in the open-circuit potential as a result of the passage of current (ASTM, 2007a). In the polarization resistance test, the impressed current to cause a small change in the value of the half-cell potential of the corroding bar is measured. For a small perturbation about the open-circuit potential, a linear relationship exists between the change in voltage (ΔE) and the change in **current per unit area** of bar surface (Δi). This ratio is called the *polarization resistance* (R_p):

$$R_p = \frac{\Delta E}{\Delta i} \quad (21.33)$$

Because the current is expressed per unit surface area of bar that is polarized, the units of R_p are ohms times area. It has been pointed out that R_p is not a resistance in the usual sense of the term (Stern and Roth, 1957), but the term is widely used (ASTM, 2007a). The underlying relationships between the corrosion rate of the bar and the polarization resistance were established by Stern and Geary (1957). No attempt is made to explain these relationships, but in simple terms the corrosion rate is inversely related to the polarization resistance. The corrosion rate is usually expressed as a corrosion current per unit area of bar, and it is determined as follows:

$$i_{\text{corr}} = \frac{B}{R_p} \quad (21.34)$$

FIGURE 21.30 Three-electrode, linear polarization method to measure corrosion current.

where:

i_{corr} = corrosion rate (ampere per square centimeter).

B = a constant (volts).

R_p = polarization resistance (ohms per square centimeter).

The constant B is a characteristic of the corrosion system, and a value of 0.026 V is commonly used for corrosion of steel in concrete (Feliú et al., 1989). This value, however, is appropriate for actively corroding bars, and a value of 0.050 V is more accurate under less active conditions (Broomfield, 1996; Feliú et al., 1996). Thus, there is inherent uncertainty of a factor of 2 in corrosion rate measurements based on Equation 21.34 if a fixed value of B is used.

It is possible to convert the corrosion rate into the thickness of steel that corrodes per unit of time. Based on Faraday's second law of electrolysis, a corrosion current density of $1 \mu\text{A}/\text{cm}^2$ corresponds to a loss of about 0.012 mm/year of steel (Andrade and Alonso, 2004). This assumes that corrosion occurs uniformly over the bar, but pitting rates can be up to 10 times greater than the uniform rate.

Figure 21.30 provides a schematic of basic apparatus for measuring the polarization resistance (Clear, 1989; Escalante, 1989). It is composed of three electrodes. One electrode is a *reference half cell*. The reinforcement is the second electrode, referred to as the *working electrode*. The third electrode, the *counter electrode*, surrounds the reference electrode and supplies the polarization current to the bar. Supplementary instrumentation measures the voltages and currents during different stages of the test. Such a device can be operated in the **potentiostatic** mode, in which the current is varied to maintain constant potential of the working electrode, or it can be operated in the **galvanostatic** mode, in which the potential is varied to maintain constant current from the counter electrode to the working electrode.

FIGURE 21.31 Linear polarization method using a guard electrode to confine polarization current.

The procedure for using such a three-electrode device to obtain the polarization resistance was provided by Cady and Gannon (1992). The basic steps are as follows:

- Locate the reinforcing-steel grid with a covermeter and mark it on the concrete surface.
- Make an electrical connection to the reinforcement (the working electrode).
- Locate the bar for which the corrosion rate is to be measured, wet the surface, and position the device over the center of the bar.
- Measure the half-cell potential of the reinforcement relative to the reference electrode (Figure 21.30a).
- Measure the current from the counter electrode to the working electrode that is necessary to produce a -4 -mV change in the potential of the working electrode (Figure 21.30b).
- Repeat the previous step for values of potential of -8 and -12 mV beyond the corrosion potential.
- Determine the surface area of bar that is affected by the measurement (perimeter of bar multiplied by the length below the counter electrode).
- Plot the potential vs. the current per unit surface area of the bar, and determine the slope of the best-fit straight line. This is the polarization resistance.

A major uncertainty in obtaining the polarization resistance is the area of the steel bar that is affected by the polarization current. In the application of the three-electrode device, it is assumed that electrons flow in straight lines perpendicular to the bar (working electrode) and the counter electrode. The bar area affected during the test is the bar circumference multiplied by the length of the bar below the counter electrode. Numerical simulations of the polarization resistance test show that the above assumption is incorrect and that the current lines are not confined to the region directly below the counter electrode (Feliú et al., 1989; Flis et al., 1992). In an effort to better control the current path from the counter electrode to the bar, a device has been developed that includes a fourth electrode, called a *guard* or *auxiliary electrode*, that surrounds the counter electrode (Feliú et al., 1990a,b). Figure 21.31 provides a schematic showing the guard electrode outside the counter electrode. The guard electrode is maintained at the same potential as the counter electrode, and, as a result, the current from the counter electrode to the working electrode is confined to the region below the counter electrode.

A drawback of the above method to measure polarization resistance is the time required for data collection. For each increment in polarization current, sufficient time is necessary to reach a steady-state condition. The duration of current application to obtain a valid measurement may vary from 30 to 100 s, depending on whether there is active or less active corrosion, respectively (Andrade and Alonso, 2004). Typically the current is applied for 100 s and it takes from 3 to 5 minutes to complete a polarization resistance measurement at each test point (Tang, 2002).

FIGURE 21.32 Galvanostatic pulse method: (a) Randles' circuit model to represent polarization of steel reinforcement; (b) change in voltage due to application of current pulse.

Another approach is to determine polarization resistance from measuring the response during the application of a short-duration current pulse. This is called the *galvanostatic pulse method* (Frølund et al., 2002). The instrumentation is similar to that shown in Figure 21.31, except that the voltage response to the applied current is measured over a short period of time (e.g., 10 s). The polarization resistance is obtained from the assumption that the polarization of the bar can be modeled by a simple electrical circuit, known as *Randles' circuit*, as shown in Figure 21.32a (Andrade and Alonso, 2004). When current is applied to this circuit, the voltage–time history across the circuit is given by the following:

$$\Delta E = I_p \left[R + R_p \left(1 - e^{\frac{-t}{R_p C}} \right) \right] \quad (21.35)$$

where:

ΔE = voltage change (V).

I_p = applied polarization current (A).

R = electrical resistance of concrete between counter electrode and bar (Ω).

R_p = polarization resistance (Ω).

C = capacitance of double layer and concrete–bar interface (F).

Figure 21.32b shows an example of a measured voltage history for an applied current pulse (Frølund et al., 2002). By means of regression analysis, Equation 21.35 is fitted to the measured voltage–time data, and the best-fit values of the three components of the equivalent Randles' circuit are obtained. In this way, the polarization resistance is determined, and, after multiplying by the polarized area of the bar, Equation 21.34 is used to determine the corrosion rate.

The pulse technique has the advantage of reducing the measurement time; however, the value of the calculated polarization resistance increases as the pulse duration (and duration of data acquisition) increases (Tang, 2002). This means that the corrosion rate will be overestimated for short pulses. It has also been found, however, that a well-defined relationship exists between polarization duration and polarization resistance, and procedures have been developed for converting measurements made at short durations to measurements made over a longer duration (Tang, 2002).

The corrosion rate based on measuring the polarization resistance represents the corrosion rate at the time of the test. The corrosion rate at a particular point in a structure is expected to depend on several factors, such as the moisture content of the concrete, the availability of oxygen, and the temperature. For this reason, the corrosion rate at any point in an exposed structure would be expected to have seasonal variations. Such variations were observed during multiple measurements that extended over a period of more than a year (Clemeña et al., 1992). A single corrosion rate measurement is unsuitable for predicting

future corrosion behavior (So et al., 2006). To project the amount of corrosion that would occur after an extended period, it is necessary to repeat the corrosion-rate measurements at different times of the year to obtain an estimate of the average rate.

No standard methods are available for interpreting corrosion-rate measurements obtained with different devices. A qualified corrosion specialist should be consulted when planning and interpreting a corrosion-rate survey; for example, based on years of experience in the laboratory and from field testing, Clear (1989) developed guidelines for interpreting measurements obtained with a specific corrosion-rate device. Additional information is provided in the comprehensive review of corrosion rate test methods prepared by Andrade and Alonso (2004).

Other limitations that should be considered when planning corrosion-rate testing have been outlined by Cady and Gannon (1992):

- The concrete surface has to be smooth (not cracked, scarred, or uneven).
- The concrete surface has to be free of water-impermeable coatings or overlays.
- The cover depth has to be less than 100 mm.
- The reinforcing steel cannot be epoxy coated or galvanized.
- The steel to be monitored has to be in direct contact with the concrete.
- The reinforcement cannot be cathodically protected.
- The reinforced concrete must not be near areas of stray electric currents or strong magnetic fields.
- The ambient temperature must be between 5 and 40°C.
- The concrete surface at the test location must be free of visible moisture.
- Test locations must not be closer than 300 mm to discontinuities, such as edges and joints.

21.3.7 Nuclear (Radioactive) Methods

Nuclear (or radioactive) methods for nondestructive evaluation of concrete involve the use of high-energy electromagnetic radiation to gain information about the internal structure of the test object. These methods involve a source of penetrating electromagnetic radiation and a sensor to measure the intensity of the radiation after it has traveled through the object. If the sensor is in the form of special photographic film, the technique is called *radiography*. If the sensor is an electronic device that converts the incident radiation into electrical pulses, the technique is called *radiometry*. A review of the early developments in the use of nuclear methods was presented by Malhotra (1976), and more recent developments have been reviewed by Mitchell (2004). Initial work in the late 1940s focused on the use of x-rays to produce radiographs of the internal structure of concrete elements, but in the 1950s attention turned to the use of gamma rays. The fundamental differences between these two forms of penetrating radiation are the sources used to generate them and their penetrating ability. X-rays are produced by high-voltage electronic devices, and gamma rays are produced by the byproducts of the decay of radioactive isotopes. The penetrating ability of gamma rays depends on the radioactive isotope and its age, but the penetration of x-rays depends on the voltage used by the generating instrument. Some of the earliest reported work using gamma rays was at Ontario Hydro (de Hass, 1954). Slabs were constructed with artificial flaws, a pipe containing a radioactive isotope of cobalt was placed beneath the slab, and a Geiger–Müller tube was placed on the top surface of the slab to measure the intensity of radiation. Other early efforts at using gamma-ray methods took place in Great Britain during the 1950s, where they were used to locate reinforcing bars, measure density, and locate voids in grouted post-tensioning tendons (Forrester, 1970). Eastern Europe and the Soviet Union also conducted early studies that eventually led to the development of portable density meters for concrete and soil.

21.3.7.1 Radiometric Methods

Two basic radiometric methods use x-rays and gamma rays for the nondestructive testing of concrete. In the **transmission** method, the amplitude of the radiation passing through a member is measured. As radiation passes through a member, the attenuation depends on the density of the material and the path length through the material. Direct transmission techniques can be used to detect reinforcement. The

main use of the technique, however, is to measure the in-place density of fresh or hardened concrete. Structures of high density and roller-compacted concretes are cases where this method is of particular value. For such applications, the radioactive source is contained in a tube that is pushed into the fresh concrete, and the detector is set on the surface of the concrete. The density meter developed at the Technical University of Brno (Czechoslovakia) is an example of such a device (Honig, 1984). The source can be lowered up to a depth of 200 mm into a hollow steel needle that is pushed into the fresh concrete. A spherical lead shield suppresses the radiation when the source is in its retracted position. Detectors are located beneath the treads used to push the needle into the concrete. It is claimed that the instrument has a resolution of 10 kg/m^3 (Honig, 1984). ASTM C 1040 (ASTM, 2005) provides procedures for using nuclear methods to measure the in-place density of fresh or hardened concrete. The key element of the procedure is development of the calibration curve for the instrument. This is accomplished by making test specimens of different densities and determining the gauge output for each specimen. The gauge output is plotted as a function of the density, and a best-fit curve is determined.

In the **backscatter** method, a radioactive source is used to supply gamma rays, and a detector close to the source is used to measure the backscattered rays. The scattered rays are of lower energy than the transmitted rays and are produced when a photon collides with an electron in an atom. Part of the photon energy is imparted to the electron, and a new photon emerges, traveling in a new direction with lower energy. This process is known as *Compton scattering* (Mitchell, 2004). Backscatter techniques are particularly suitable for applications where a large number of *in situ* measurements are required. Because backscatter measurements are affected by the top 40 to 100 mm, the method is best suited for measurement of the surface zone of a concrete element. A good example of the use of this method is monitoring the density of bridge deck overlays. Non-contacting equipment has been developed that is used for continuous monitoring of concrete pavement density during slip-form operations (Mitchell et al., 1979).

Procedures for using backscatter methods to measure concrete density are given in ASTM C 1040 (ASTM, 2005). As is the case with direct transmission measurements, it is necessary to establish a calibration curve before using a nuclear backscatter gauge to measure in-place density. The inherent precision of backscatter density gauges is less than that of direct transmission devices. ASTM C 1040 requires that a suitable backscatter gauge for density measurement result in a standard deviation of less than 16 kg/m^3 , whereas the standard deviation should be less than 8 kg/m^3 for a direct-transmission gauge. According to ASTM C 1040, backscatter gauges are influenced typically by the top 75 to 125 mm of material. The top 25 mm determines 50 to 70% of the count rate, and the top 50 mm determines 80 to 95% of the count rate.

21.3.7.2 Radiographic Methods

Radiography provides a radiation-based photograph of the interior of concrete from which the location of reinforcement, voids in concrete, or voids in grouted post-tensioning tendons can be identified. A radiation source is placed on one side of the test object, and a beam of radiation is emitted. As the radiation passes through the member, it is attenuated by different amounts, depending on the density and thickness of the material that is traversed. The radiation that emerges from the opposite side of the object strikes a special photographic film that is exposed in proportion to the intensity of the incident radiation. When the film is developed, a two-dimensional visualization (a photograph) of the interior structure of the object is obtained. The presence of high-density material, such as reinforcement, is shown on the developed film as a light area, and a region of low density, such as a void, is shown as a dark area.

The British Standards Institution has adopted a standard for radiographic testing of concrete (BS 1881, Part 205, Recommendations for Radiography of Concrete). The standard provides recommendations for investigators considering radiographic examinations of concrete (Mitchell, 2004). In x-radiography, the radiation is produced by an x-ray tube. The penetrating ability of the x-rays depends on the operating voltage of the x-ray tube. In gamma radiography, a radioactive isotope is used as the radiation source. The selection of a source depends on the density and thickness of the test object and on the exposure time that can be tolerated. The most intense source is cobalt-60, which can be used to penetrate up to 500 mm of concrete. For members with thickness of 150 mm or less, iridium-192 or cesium-137 can be used

(Mitchell, 2004). The film type will depend on the thickness and density of the member being tested. Most field applications have used radioactive sources because of their greater penetrating ability (higher energy radiation) compared with x-rays; however, a system known as Scorpion II was developed in France that uses a linear accelerator to produce very high-energy x-rays than can penetrate up to 1 m of concrete. This system was developed for the inspection of prestressed members to establish the condition and location of prestressing strands and to determine the quality of grouting in tendon ducts (Mitchell, 2004).

21.3.7.3 Summary

Whereas nuclear methods have the ability to see into concrete, they are cumbersome and require trained and licensed personnel (Mitchell, 2004.). Testing across the full thickness of a concrete element is particularly hazardous and requires extensive precautions, skilled personnel, and highly specialized equipment. Radiographic procedures are costly and require evacuation of the structure by persons not involved in the actual testing. The use of x-ray equipment poses an additional danger due to the high voltages that are used. There are limits on the thicknesses of the members that can be tested by radiographic methods. For gamma-ray radiography, the maximum thickness is about 500 mm, because thick members require unacceptably long exposure times. Radiography is not very useful for locating crack planes perpendicular to the radiation beam. Because of these major drawbacks, radiographic methods are not used routinely for flaw detection; however, in some situations the ability to see the internal structure of the member surpasses these drawbacks.

21.4 Concluding Remarks

This chapter has summarized the available nondestructive techniques for assessing the properties or condition of concrete in structures. The techniques have been divided into two groups:

- Those used for estimating the in-place strength, and
- Those used for flaw detection and condition assessment.

Emphasis has been placed on describing their underlying principles and highlighting some of their inherent limitations. The user is referred to applicable publications of the American Concrete Institute and relevant ASTM standards for additional information on using these methods.

The key feature of the methods for estimating in-place strength is the strength relationship that correlates concrete strength to the results of the in-place tests. The strength relationship should be developed experimentally before using the test method to estimate in-place strength. For new construction, test specimens should be made of concrete similar to what will be used in the structure. Care must be exercised to ensure that the companion in-place tests and standard strength tests are carried out on specimens of the same maturity at each strength level. For existing construction, it is necessary to perform in-place tests and obtain cores at different locations so a wide range of concrete strengths can be used to develop the strength relationship. After the strength relationship has been established, in-place tests are done on the structure, and statistical methods are used to convert the average in-place test result to a reliable estimate of in-place strength. Generally, in-place test methods that result in local failure of the concrete are more reliable than those that are totally nondestructive.

A variety of methods are available for flaw detection and condition assessment. Most of these methods are based on monitoring the response of the structure when it is subjected to some type of disturbance. Two broad classes of nondestructive methods are those based on stress-wave propagation and those based on electromagnetic-wave propagation. Except for visual inspection, these methods generally require sophisticated instrumentation. All nondestructive test methods have inherent strengths and weaknesses. It is often advantageous to use more than one method to make the assessment. Methods based on stress-wave propagation are suited for identifying the presence of internal concrete–air interfaces, such as those due to cracking or voids. An understanding of the basics of stress-wave propagation is essential for proper interpretation of test results. Electrical methods are well suited for gaining information about embedded

reinforcement, such as location, approximate size, and whether active corrosion exists. Radar is appropriate for finding deep metallic embedments and is also sensitive to the presence of moisture. Radar has the added advantage that large portions of a structure can be scanned in a short time.

The importance of having qualified operators cannot be overemphasized. Nondestructive tests are indirect methods by which the property or characteristic of primary interest is inferred by measuring other properties or characteristics. A lack of understanding of the underlying principles and the interferences associated with the method can lead to incorrect assessments of the concrete. When used by properly trained operators, nondestructive test methods offer technical and economic advantages compared with other invasive sampling techniques.

Hexagon marine structure in Kanagawa, Japan, comprised of concrete floating block reinforced with glass-fiber-reinforced plastic (GFRP) tendons. The tendons consist of nine multi-cables, each made of eight 0.3-in. (8-mm) diameter GFRP rods. The concrete floating blocks were connected by post-tensioning GFRP tendons, and the anchorage was provided by using multi-type anchor heads and wedges. Construction was completed in 1993. Part A. Fiber-Reinforced Concrete

22.1 Historical Development

Fibers have been used to reinforce brittle materials from time immemorial, dating back to the Egyptian and Babylonian eras, if not earlier. Straws were used to reinforce sun-baked bricks and mud-hut walls, horse hair was used to reinforce plaster, and asbestos fibers have been used to reinforce Portland cement mortars. Research in the late 1950s and early 1960s by Romualdi and Batson (1963) and Romualdi and Mandel (1964) on closely spaced random fibers, primarily steel fibers, heralded the era of using the fiber composite concretes we know today. In addition, Shah and Rangan (1971), Swamy (1975), and several other researchers in the United States, United Kingdom, Japan, and Russia embarked on extensive investigations in this area, exploring other fibers in addition to steel. By the 1960s, steel-fiber concrete began to be used in pavements, in particular. Other developments using bundled fiberglass as the main composite reinforcement in concrete beams and slabs were introduced by Nawy et al. (1971) and Nawy and Neuwerth (1977), as discussed in Section 22.8 of this chapter. From the 1970s to the present, the use of steel fibers has been well established as a complementary reinforcement to increase cracking resistance, flexural and shear strength, and impact resistance of reinforced concrete elements both *in situ* cast and precast.

22.2 General Characteristics

Concrete is weak in tension. Microcracks begin to generate in the matrix of a structural element at about 10 to 15% of the ultimate load, propagating into macrocracks at 25 to 30% of the ultimate load. Consequently, plain concrete members cannot be expected to sustain large transverse loading without the addition of continuous-bar reinforcing elements in the tensile zone of supported members such as beams or slabs. The developing microcracking and macrocracking, however, still cannot be arrested or slowed by the sole use of continuous reinforcement. The function of such reinforcement is to replace the function of the tensile zone of a section and assume the tension equilibrium force in the section. The addition of randomly spaced discontinuous fiber elements should aid in arresting the development or propagation of the microcracks that are known to generate at the early stages of loading history. Although fibers have been used to reinforce brittle materials such as concrete since time immemorial, newly developed fibers have been used extensively worldwide in the past three decades. Different types are commercially available, such as steel, glass, polypropylene, or graphite. They have proven that they can improve the mechanical properties of the concrete, both as a structure and a material, not as a replacement for continuous-bar reinforcement when it is needed but in addition to it.

Concrete fiber composites are concrete elements made from a mixture comprised of hydraulic cements, fine and coarse aggregates, pozzolanic cementitious materials, admixtures commonly used with conventional concrete, and a dispersion of discontinuous, small fibers made from steel, glass, organic polymers, or graphites. The fibers could also be vegetable fibers such as sisal or jute. Generally, if the fibers are made from steel, the fiber length varies from 0.5 to 2.5 in. (12.7 to 63.5 mm). They can be round, produced by cutting or chopping wire, or they can be flat, typically having cross-sections 0.006 to 0.016 in. (0.15 to 0.41 mm) in thickness and 0.01 to 0.035 in. (0.25–0.90 mm) in width and produced by shearing sheets or flattening wire. The most common diameters of the round wires are in the range of 0.017 to 0.040 in. (0.45 to 1.0 mm) (ACI Committee 544, 1988, 1993, 1996). The wires are usually crimped or deformed or have small heads on them for better bond within the matrix, and some are crescent shaped in cross-section.

The fiber content in a mixture where steel fibers are used usually varies from .25 to 2% by volume—namely, from 33 to 265 lb/yd³ (20 to 165 kg/m³). A fiber content of 50 to 60 lb/yd³ is common in lightly loaded slabs on grade, precast elements, and composite steel deck topping. The upper end of the range, more difficult to apply, is used for security applications such as vaults, safes, and impact-resisting structures.

TABLE 22.1 Typical Properties of Fibers

Type of Fiber (1)	Diameter, in. $\times 10^3$ (mm) (2)	Specific Gravity ^a (3)	Tensile Strength, psi $\times 10^3$ (GPa) (4)	Young's Modulus, psi $\times 10^6$ (GPa) (5)	Ultimate Elongation (%) (6)
Acrylic	0.6–0.13 (0.02–0.35)	1.1	30–60 (0.2–0.4)	0.3 (2)	1.1
Asbestos	0.05–0.80 (0.0015–0.02)	3.2	80–140 (0.6–1.0)	12–20 (83–138)	1–2
Cotton	6–24 (0.2–0.6)	1.5	60–100 (0.4–0.7)	0.7 (4.8)	3–10
Glass	0.2–0.6 (0.005–0.15)	2.5	150–380 (1.0–2.6)	10–11.5 (70–80)	1.5–3.5

Source: Nawy, E.G., *Fundamentals of High-Strength, High-Performance Concrete*, Addison Wesley Longman, Reading, MA, 1996, p. 350.

The introduction of fiber additions to concrete in the early 1900s was aimed primarily at enhancing the tensile strength of concrete. As is well known, the tensile strength is 8 to 14% of the compressive strength of normal concretes with resulting cracking at low stress levels. Such a weakness is partially overcome by the addition of reinforcing bars, which can be either steel or fiberglass, as **main continuous reinforcement** in beams and one-way and two-way structural slabs or slabs on grade (Nawy and Neuwerth, 1977; Nawy et al., 1971). As indicated earlier, the continuous reinforcing elements cannot stop the development of microcracks. Fibers, on the other hand, are discontinuous and randomly distributed in the matrix, in both the tensile and compressive zones of a structural element. They are able to add to the stiffness and crack-control performance by preventing the microcracks from propagating and widening and also by increasing ductility due to their energy-absorption capacity. Common applications of fiber-reinforced concrete include overlays in bridge decks, industrial floors, shotcrete applications, highway and airport pavements, thin-shell structures, seismic- and explosion-resisting structures, super flat surface slabs on grade in warehouses, and for the reduction of expansion joints. Table 22.1 describes the geometry and mechanical properties of various types of fibers that can be used as randomly dispersed filaments in a concrete matrix. Because of the wide range of properties for each type of fiber, the designer should be guided by the manufacturer's data on each particular product and experience with it before a fiber type is selected.

TABLE 22.2 Typical Proportions for Normal Weight Fiber-Reinforced Concrete

Material	Range
Cement	550–950 lb/yd ³
W/C ratio	0.4–0.6
Percentage of sand to aggregate	50–100%
Maximum aggregate	3/8 in.
Air content	6–9%
Fiber content	0.5–2.5% by volume of mix (steel, 1% = 132 lb/yd ³ ; glass, 1% = 42 lb/yd ³ ; nylon, 1% = 19 lb/yd ³)

Note: 1 lb/yd³ = 0.5933 kg/m³; 1 in. = 2.54 cm.

22.3 Mixture Proportioning

Mixing the fibers with the other mix constituents can be done by several methods. The method selected—plant batching, ready-mixed concrete, or hand mixing in the laboratory—depends on the facilities available and the job requirements. The most important factor is to ensure **uniform dispersion** of the fibers and to prevent segregation or balling of the fibers during mixing. Segregation or balling during mixing is affected by many factors, which can be summarized as follows:

- Aspect ratio (ℓ/d_f), which is most important
- Volume percentage of the fiber
- Coarse aggregate size, gradation, and quantity
- Water/cementitious materials ratio and method of mixing

A maximum aspect ratio of ℓ/d_f and a steel fiber content in excess of 2% by volume make it difficult to achieve a uniform mix. Although conventional mixing procedures can be used, it is advisable to use a 3/8-in. (9.7-mm) maximum aggregate size. The water requirement will vary from that of concrete without fibers depending on the type of cement replacement cementitious pozzolans used and their percent by volume of the matrix. Table 22.2 and Table 22.3 give typical mixture proportions for normal weight fibrous reinforced concrete and fly-ash fibrous concrete mixes, respectively. A workable method for mixing in a step-by-step chronological procedure can be summarized as follows:

- Blend part of the fiber and aggregate before charging into the mixer.
- Blend the fine and coarse aggregate in the mixer, add more fibers at mixing speed, then add cement and water simultaneously or add the cement immediately followed by water and additives.

FIGURE 22.1 Schematic load–deflection relationship of fiber-reinforced concrete.

- Add the balance of the fiber to the previously charged constituents, and add the remaining cementitious materials and water.
- Continue mixing as required by normal practice.
- Place the fibrous concrete in the forms. Use of fibers requires more vibrating than required in nonfibrous concrete; although internal vibration is acceptable if carefully applied, external vibration of the formwork and the surface is preferable to prevent segregation of the fibers.

22.4 Mechanics of Fiber Reinforcement

22.4.1 First Cracking Load

Fiber-reinforced concrete in flexure essentially undergoes a trilinear deformation behavior as shown in Figure 22.1. Point A on the load-deflection diagram represents the first cracking load, which can be termed the *first-crack strength* (Mindess and Young, 1981). Normally, this is the same load level at which a nonreinforced element cracks; hence, segment OA in the diagram would be the same and essentially have the same slope for both plain and fiber-reinforced concrete. Once the matrix is cracked, the applied load is transferred to the fibers that bridge and tie the crack to keep it from opening further. As the fibers deform, additional narrow cracks develop, and continued cracking of the matrix takes place until the maximum load reaches point B of the load-deflection diagram. During this stage, debonding and pullout of some of the fibers occur, but the yield strength in most of the fibers is not reached. In the falling branch, BC, of the load-deflection diagram, matrix cracking and fiber pullout continue. If the fibers are long enough to maintain their bond with the surrounding gel, they may fail by yielding or by fracture of the fiber element, depending on their size and spacing.

22.4.2 Critical Fiber Length: Length Factor

If l_c is the critical length of a fiber above which the fiber fractures instead of pulling out when the crack intersects the fiber at its midpoint, it can be approximated by (Mindess and Young, 1981):

$$\ell_c = \frac{d_f}{2\nu_b} \sigma_f \quad (22.1)$$

where:

- d_f = fiber diameter.
- ν_b = interfacial bond strength.
- σ_f = fiber strength.

Bentur and Mindess (1990) developed an expression to relate the average pullout work and the fiber matrix interfacial bond strength in terms of the critical fiber length, demonstrating that the strength of

FIGURE 22.2 Effect of steel-fiber spacing on the tensile cracking stress in fibrous concrete for $\rho = 2.5, 5.9$, and 7.5% . (From Romualdi, J.P. and Batson, G.B., *Proc. ASCE Eng. Mech. J.*, 89(EM3), 147–168, 1963.)

a composite increases continuously with the fiber length. This is of significance as it indicates that pullout work may go through a maximum and then decreases as bond strength increases over a critical value. This loss of pullout work would be reduced to a typical range of $\ell = 10$ mm in the cement-based composites discussed in Section 22.6. If a critical v_b value of 1.0 MPa and a small-diameter fiber (e.g., $d_f = 20$ μm) are chosen, then an increase in bond may result in reduced toughness.

22.4.3 Critical Fiber Spacing: Space Factor

The spacing of the fibers considerably affects cracking development in the matrix. The closer the spacing, the higher the first cracking load of the matrix. This is due to the fact that the fibers reduce the stress-intensity factor that controls fracture. The approach taken by Romualdi and Batson (1963) to increase the tensile strength of the mortar was to increase the stress-intensity factor by decreasing the spacing of the fibers acting as crack arresters. Figure 22.2 relates the tensile cracking stress to the spacing of the fibers for various volumetric percentages. Figure 22.3 compares the theoretical and experimental values of the ratio of the first cracking load to the cracking strength of plain concrete (strength ratio). Both diagrams demonstrate that the strength ratio increases as the spacing of the fibers is reduced; that is, the tensile strength of the concrete increases up to the practical workability and cost-effectiveness limits. Various shapes and sizes of steel fibers are shown in Figure 22.4.

Several expressions to define the spacing of the fibers have been developed. If s is the spacing of the fibers, one expression from Romualdi and Batson (1963) gives:

$$s = 13.8d_f \sqrt{\frac{1.0}{\rho}} \quad (22.2)$$

where:

d_f = diameter of the fiber.

ρ = fiber percent by volume of the matrix.

Another expression due to McKee (1969) gives:

$$s = 3 \sqrt{\frac{V}{\rho}} \quad (22.3)$$

FIGURE 22.3 Effect of fiber spacing on the strength ratio. Ratio equals first cracking load of fibrous concrete divided by strength of plain concrete. (From Romualdi, J.P. and Mandel, J.A., *Proc. ACI J.*, 61(6), 657–671, 1964.)

FIGURE 22.4 Various shapes and sizes of steel fibers.

where V is the volume of one fiber element. An expression that also takes into account the length of the fiber gives (Mindess and Young, 1981):

$$s = 13.8d_f \frac{\sqrt{\ell}}{\rho} \tag{22.4}$$

22.4.4 Fiber Orientation: Fiber Efficiency Factor

The orientation of the fibers with respect to load determines the efficiency with which the randomly oriented fibers can resist the tensile forces in their directions. This observation is synonymous with the contribution of bent bars and vertical shear stirrups provided in beams to resist the inclined diagonal tension stress. If one assumes perfect randomness, the efficiency factor is $0.41l$, but it can vary between $0.33l$ and $0.65l$ close to the surface of the specimen, as trowling or leveling can modify the orientation of the fibers (Mindess and Young, 1981).

22.4.5 Static Flexural Strength Prediction: Beams with Fibers Only

To predict flexural strength, several methods could be applied depending on the type of fiber, the type of matrix, whether empirical data from laboratory experiments are used, or whether the design is based on the bonded area of the fiber or the law of mixtures. An empirical expression for the composite flexural strength based on a composite-material approach is (Bentur and Mindess, 1990):

$$\sigma_c = A\sigma_m(1 - V_f) + BV_f \frac{\ell}{d} \quad (22.5)$$

where:

- σ_c = composite flexural strength.
- σ_m = ultimate strength of the matrix.
- V_f = volume fraction of the fibers adjusted for the effect of randomness.
- A, B = constants.
- ℓ/d = aspect ratio of the fiber, where l is the length and d is the diameter of the fiber.

The constants A and B were obtained from $4 \times 4 \times 12$ -in. ($100 \times 100 \times 305$ -mm) model beam tests by Swamy et al. (1974) and were adopted by ACI Committee 544 (1993). These constants lead to the following expressions:

First crack composite flexural strength (psi):

$$\sigma_f = 0.843f_r V_m + 425V_f \frac{\ell}{d_f} \quad (22.6)$$

where:

- f_r = stress in the matrix (modulus of rupture of the plane mortar or concrete) (lb/in.²).
- V_m = volume fraction of the matrix = $1 - V_f$.
- V_f = volume fraction of the fibers = $1 - V_m$.
- ℓ/d_f = ratio of length to diameter of the fibers (i.e., the aspect ratio).

Ultimate composite flexural strength (psi):

$$\sigma_{cu} = 0.97f_r V_m + 494V_f \frac{\ell}{d_f} \quad (22.7)$$

22.5 Mechanical Properties of Fibrous Concrete Structural Elements

22.5.1 Controlling Factors

From Section 22.4, it can be seen that the mechanical properties of fiber-reinforced concretes are influenced by several factors:

FIGURE 22.5 Influence of volume fraction of steel fibers on stress–strain behavior for 13,000-psi concrete. (From Shah, S.P. and Rangan, B.V., *Proc. ACI J.*, 68(2), 126–134, 1971.)

- Type of fiber (i.e., the fiber material and its shape)
- Aspect ratio ℓ/d_f (i.e., the ratio of fiber length to nominal diameter)
- Amount of fiber in percentage by volume (ρ)
- Spacing of the fiber (s)
- Strength of the concrete or mortar matrix
- Size, shape, and preparation of the specimen

Hence, it is important to conduct laboratory tests to failure on the mixtures using specimen models similar in form to the elements being designed. As the fibers affect the performance of the end product in all material-resistance capacities such as in flexure, shear, direct tension, and impact, it is important to evaluate the test specimen performance with regard to those parameters.

The contribution of the fiber to tensile strength, as discussed in Section 22.3, is due to its ability to act as reinforcement and assume the stress from the matrix when it cracks through the interface shear friction interlock between the fiber and the matrix. This phenomenon is analogous to the shear friction interlock hypothesis presented in Nawy (1996) in his discussion on the mechanism of shear friction interlock. Deformed or crimped fibers have a greater influence than smooth and straight ones. The pullout resistance in zone AB of Figure 22.1 is proportional to the interfacial surface area (ACI Committee 544, 1993). The non-round fiber cross-sections and the smaller diameter round fibers induce a larger resistance per unit volume than the larger diameter fibers. This is also analogous to the crack-control behavior in traditionally reinforced structural members, where a larger number of smaller diameter bars that are more closely spaced is more effective than a smaller number of large diameter bars for the same reinforcement volume percentage (Nawy and Blair, 1971). One reason for this is the larger surface interaction area between the fibers and the surrounding matrix, resulting in a higher bond and shear friction resistance.

22.5.2 Strength in Compression

The effect of the contribution of the fibers to the compressive strength of the concrete seems to be minor, as seen in Figure 22.5 (Hsu and Hsu, 1994) for tests using steel fibers; however, the ductility and toughness are considerably enhanced as a function of the increase in the volume fractions and aspect ratios of the fibers used. Figure 22.5 shows the effect of an increase in volume fraction on the stress–strain relationship of the fibrous concrete resulting from an increase in the fiber volume from 0 to 1.5% for concretes having a compressive strength of 13,100 psi (90.3 MPa). Figure 22.6 and Figure 22.7 depict a similar trend with

FIGURE 22.6 Influence of volume fraction of steel fibers on stress–strain behavior for 9000 psi concrete. (From Fanella, D.A. and Naaman, A.E., *ACI J.*, 82(4), 475–483, 1985.)

FIGURE 22.7 Influence of aspect ratio of steel fibers on stress–strain behavior. (From Fanella, D.A. and Naaman, A.E., *ACI J.*, 82(4), 475–483, 1985.)

respect to both a volume fraction ratio up to 3% and an aspect ratio in the range of 47 to 100. Figure 22.8 also demonstrates the influence of the increase in fiber content on the relative toughness of reinforced concrete members.

Toughness is a measure of the ability to absorb energy during deformation. It can be estimated from the area under the stress–strain or load–deformation diagrams. A toughness index (TI) expression proposed by Hsu and Hsu (1994) follows:

$$TI = 1.421RI + 1.035 \quad (22.8)$$

where:

RI = reinforcing index = $V_f(\ell/d_f)$.

V_f = volume fraction.

ℓ/d_f = aspect ratio.

Figure 22.9 illustrates the relationship of the toughness index to the reinforcing index of fibrous high-strength concretes within the limitations of the type, aspect ratio, and volume fractions of the steel fibers used in those tests. In short, by increasing the volume fraction, both ductility and toughness have been shown to increase significantly within the practical limits of workable volume content of fiber in a concrete mix.

FIGURE 22.8 Relative toughness and strength vs. fiber volume ratio. (From Shah, S.P. and Rangan, B.V., *Proc. ACI J.*, 68(2), 126–134, 1971.)

FIGURE 22.9 Toughness index vs. reinforcing index of fibrous concrete. (From Shah, S.P. and Rangan, B.V., *Proc. ACI J.*, 68(2), 126–134, 1971.)

22.5.3 Strength in Direct Tension

The effect of different shapes of the fiber filaments on the tensile stress behavior of steel-fiber-reinforced mortars in direct tension is demonstrated in Figure 22.10. The descending portion of the plots show that the fibers reinforced with better anchorage quality increase the tensile resistance of the fiber-reinforced concrete beyond the first cracking load.

FIGURE 22.10 Effect of the shape of steel fibers on tensile stress in mortar specimens loaded in direct tension. (From Shah, S.P. and Rangan, B.V., *Proc. ACI J.*, 68(2), 126–134, 1971.)

22.5.4 Flexural Strength

Fibers seem to affect the magnitude of flexural strength in concrete and mortar elements to a much greater extent than they affect the strength of comparable elements subjected to direct tension or compression (ACI Committee 544, 1993). Two stages of loading portray the behavior. The first controlling stage is the **first cracking load stage** in the load-deflection diagram, and the second controlling stage is the ultimate load stage. Both the first cracking load and the ultimate flexural capacity are affected as a function of the product of the fiber volume concentration (ρ) and the aspect ratio (ℓ/d_f). Fiber concentrations less than .5% of the volume of the matrix and with an aspect ratio less 50 seem to have a small effect on the flexural strength, although they can still have a pronounced effect on the toughness of the concrete element, as seen in Figure 22.8. The flexural strength of plain concrete beams containing steel fibers was defined in Equation 22.6 and Equation 22.7. For structural beams reinforced with both normal reinforcing bars and fibers added to the matrix, a modification of the standard expression for nominal moment strength, $M_n = A_s f_y (d - a/2)$, must be made to account for the shear friction interaction of the fibers in preventing the flexural macrocracks from opening and propagating in the tensile zone of the concrete section, as seen in Figure 22.11 (Henager and Doherty, 1976). In this diagram, the area of concrete in the tensile zone is neglected and an additional equilibrium tensile force (T_{fc}) is added to the section. This moves the neutral axis down, leading to a higher nominal moment strength (M_n). The resulting expression for M_n becomes (Henager and Doherty, 1976):

$$M_n = A_s f_y \left(d - \frac{a}{2} \right) + \sigma_t b (h - e) \left(\frac{h}{2} + \frac{e}{2} - \frac{a}{2} \right) \quad (22.9)$$

$$e = \left[\epsilon(\text{fibers}) + 0.003 \right] \frac{c}{0.003} \quad (22.10)$$

$$\sigma_t \text{ (psi)} = \frac{1.12 \ell}{d_f \rho_f F_{be}} \quad (22.11a)$$

$$\sigma_t \text{ (MPa)} = \frac{0.00772 \ell}{d_f \rho_f F_{be}} \quad (22.11b)$$

where:

ℓ = fiber length.

d_f = fiber diameter.

ρ_f = percent by volume of the fibers.

F_{be} = bond efficiency of the steel fiber depending on its characteristics (varies from 1.0 to 1.2).

a = depth of the equivalent rectangular block.

b = width of beam.

FIGURE 22.11 Stress and strain distribution across depth of singly reinforced fibrous concrete beams: (a) assumed stress distribution, (b) equivalent stress block distribution, and (c) strain distribution.

c = depth to the neutral axis.

d = effective depth of the beam to the center of the main tensile bar reinforcement.

e = distance from the extreme compression fibers to the top of the tensile stress block of the fibrous concrete.

ϵ_s = f_y/E_s of the bar reinforcement.

ϵ_f = σ_f/E_c of the fibers developed at pullout at a dynamic bond stress of 333 psi.

σ_t = tensile yield stress in the fiber.

T_{fc} = tensile yield of the fibrous concrete in Figure 22.11 = $\sigma_t b(h - e)$.

T_{rb} = tensile yield force of the bar reinforcement in Figure 22.11 = $A_s f_y$.

22.5.5 Shear Strength

A combination of vertical stirrups and randomly distributed fibers in the matrix enhances the diagonal tension capacity of concrete beams. The degree of increase in the diagonal tension capacity is a function of the shear span/depth ratio of a beam. This ratio determines the mode of failure in normal beams that do not fall in the category of deep beams and brackets as detailed by Nawy (2008). Williamson (1978) found that when 1.66% by volume of straight steel fibers are used instead of stirrups, the shear capacity increased by 45% over beams without stirrups. When steel fibers with deformed ends were used at a volume ratio of 1.1%, the shear capacity increased by 45 to 67% and the beams failed by flexure. Using crimped-end fibers increased the shear capacity by almost 100%.

In general, as the shear span/depth ratio (a/d) decreases and the fiber volume increases, the shear strength increases proportionally. Tests by Sharama (1986) resulted in the following expression for the average shear stress (v_c) for beams in which steel fibers were added (ACI Committee 544, 1993):

$$v_{cf} = \frac{2}{3} f'_t \left(\frac{d}{a} \right)^{\frac{1}{4}} \quad (22.12)$$

where:

f'_t = tensile splitting strength.

d = effective depth of a beam.

a = shear span, equal to the distance from the point of application of the load to the face of the support when concentrated loads are acting or equal to the clear beam span when distributed loads are acting.

22.5.6 Environmental Effects

22.5.6.1 Freezing and Thawing

The addition of fibers to a matrix does not seem to result in an appreciable improvement in the freezing and thawing performance of concrete, as its resistance to such an environmental effect is controlled by permeability, void ratio, and freeze–thaw cycles. Fibers, however, tend to hold the scaling concrete pieces together, thereby reducing the extent of apparent scaling.

22.5.6.2 Shrinkage and Creep

No appreciable improvement in the shrinkage and creep performance of concrete results from the addition of fibers, but a slight decrease in shrinkage can result due to the need to add more paste mortar in the mixture when fibers are used. Cracking due to drying shrinkage in restrained elements can be slightly improved, as the cracks are kept from generating because of the bridging effect of the randomly distributed fibers.

22.5.7 Dynamic Loading Performance

The cracking behavior of fibrous concrete elements under dynamic loading seems to be three to ten times better than that of plain concrete. Also, the total energy absorbed by the steel fibrous concrete beams can be 40 to 100 times that for plain concrete beams, depending on the type, deformed shape, and percent volume of the fibers (ACI Committee 544, 1993).

22.6 Steel-Fiber-Reinforced Cement Composites

22.6.1 General Characteristics

Fiber-reinforced concretes are designed to contain a maximum 2% by volume of fibers, using the same mixture design procedures and placement as nonfibrous concretes. Fiber-reinforced cement composites, on the other hand, could contain a volume fraction, namely, a fiber content by volume, as high as 8 to 25%. Consequently, neither the design of the mixture nor the constituent materials in the matrix can be similar to those of conventional fibrous or nonfibrous concretes. Either cement only or cement with sand is used in the mixture, with no coarse aggregate, to achieve the high strength, ductility, and high performance expected from such composites. The 1980s saw the development of **macrodefect-free** (MDF) cements, which have a high Young's modulus and flexural strengths up to almost 30,000 psi (~200 MPa), as well as **densified small-particle** (DSP) cements, which have a particle size less than 1/20 that of Portland cement (0.5 μm). The void content in any matrix can be reduced to a negligible percentage with the addition of pozzolans such as silica fume. With these developments as a background, the following are the types of cement-based composites being studied today:

- Slurry-infiltrated fiber concrete (SIFCON) and a composite for refractory use (SIFCA®)
- Densified small-particle (DSP) systems
- Compact reinforced composite (CRC)
- Carbon-fiber-reinforced cement-based composites
- Super-strength reactive powder concrete (RPC).

These cement-based composites can achieve a compressive strength in excess of 44,000 psi (300 MPa) in compression and an energy absorption capacity (i.e., ductility) that can be up to 1000 times that of plain concrete (Reinhardt and Naaman, 1992).

22.6.2 Slurry-Infiltrated Fiber Concrete

Because of the high volume fraction of steel fibers (8 to 25%), the mixture for a structural member is formulated by sprinkling the fiber into the formwork or over a substratum. Either the substratum is stacked with fibers to a prescribed height or the form is completely or partially filled with the fibers,

FIGURE 22.12 Stress–strain relationship of SIFCON with rupture strain in the range of 0.45 in./in. (From Naaman, A.E., in *Proceedings of the International RILEM/ACI Workshop*, Reinhardt, H.W. and Naaman, A.E., Eds., Chapman & Hall, New York, 1992, pp. 18–38.)

FIGURE 22.13 Influence of matrix compressive strength on the stress–strain response of SIFCON in compression. (From Naaman, A.E., in *Proceedings of the International RILEM/ACI Workshop*, Reinhardt, H.W. and Naaman, A.E., Eds., Chapman & Hall, New York, 1992, pp. 18–38.)

depending on the requirement of the design. After the fibers are placed, a low-viscosity cement slurry is poured or pumped into the fiber bed or into the formwork, infiltrating into the spaces between the fibers. Typical cement/fly-ash/sand proportions can vary from 90/10/0 to 30/20/50 by weight (Schneider, 1992). The water/cementitious ratio, $W/(C + F)$, can range between 0.45 and 0.20 by weight, with a plasticizer content of 10 to 40 oz. per 100 lb of the total cementitious weight ($C + F$). Batch trials of the slurry mix have to be carefully made with regard to the $W/(C + F)$ ratio to arrive at a workable slurry mix that can fully penetrate the depth of the fibers. Figure 22.12 provides a stress–strain diagram for a SIFCON mixture (Naaman, 1992) with a compressive strength close to 18,000 psi but with a very large strain capability in the falling branch of the diagram. Figure 22.13 illustrates the influence of the matrix compressive strength on the stress–strain response of SIFCON in compression (Schneider, 1992). A fiber content (V_f) of 11% resulted in total uniaxial strain in excess of 10%.

22.6.3 DSP and CRC Cement Composites

Densified small-particle (DSP) systems and compact reinforced composite (CRC) gain super high strength depending largely on the type of compact-density cements that are used for the cement-based composites and the proportioning used to considerably reduce or practically eliminate most of the voids in the paste. Figure 22.14 illustrates the fracture surface of a steel-fiber-reinforced concrete specimen.

FIGURE 22.14 Fracture surface of steel-fiber-reinforced concrete. (Photograph courtesy of the American Concrete Institute, Farmington Hills, MI.)

22.6.4 Carbon-Fiber-Reinforced Cement-Based Composites

Petroleum-pitch-based carbon fibers have recently been developed for use as reinforcement for cement-based composites. Their diameters vary from 0.0004 to 0.0007 in. (10 to 18 μm), and their lengths vary from 1/8 to 1/2 in. (3 to 12 mm). Their tensile strength typically ranges from 60 to 110 ksi (400 to 750 MPa). They are incorporated in the cement-based composites in essentially the same manner as steel fibers are in concrete, and they are uniformly distributed and randomly oriented. Because of the very small size of the carbon fibers and their small diameter, a high fiber count is attained in the cementitious matrix at a typical volume fraction of 0.5 to 3% (Bayasi, 1992). The spacing between the fibers is approximately 0.004 in. (0.1 mm) at a 3% fiber volume fraction. The function of the carbon fibers function is similar to that of the steel fibers in preventing microcracks from propagating and opening.

22.6.5 Super-Strength Reactive-Powder Concretes

Super-strength reactive powder concrete (RPC) has a compressive strength ranging from 30,000 to 120,000 psi (200 to 800 MPa). The lower range is used today for the construction of structural elements. The higher ranges are used in nonstructural applications such as flooring, safes, and storage compartments for nuclear waste. Concretes in the higher ranges are termed *super-high-strength concretes* and possess the very high ductility necessary for applications in structural systems. The principal characteristic of such concretes is the use of a powder concrete in which aggregates and traditional sand are replaced by ground quartz less than 300 μm in size (Richard and Cheyrezy, 1994). In this manner, the homogeneity of the mixture is greatly improved, and the distribution in the size of the particles is consequently reduced by almost two orders of magnitude. A major improvement in the properties of the hardened concrete is an increase in the Young's modulus value of the paste by almost a factor of three so its value can reach to 6 to 11 $\times 10^{-6}$ psi (55 to 75 GPa), thereby reducing the effects of incompatibility between the moduli of the paste and the quartz powder. Richard and Cheyrezy (1994) developed the following mechanical characteristics of RPC concrete:

- Improved homogeneity resulting in a Young's modulus up to 11 $\times 10^{-6}$ psi (75 GPa)
- Increase in dry compact density of the dry solids (although silica fume, with its small particle size of 0.1 to 0.5 μm and an optimum mix content of 25% cement by weight, gives excellent dry compact density, additional amounts of precipitated silica further improve the dry compact density)

TABLE 22.4 Mixture Composition and Concrete Mechanical Properties of Super-High-Strength Reactive Powder Concrete

Mixture Constituents	RPC 200 Concrete lb/yd ³ (MPa)	RPC 800 Concrete lb/yd ³ (MPa)
Portland cement, Type V	1614 (955)	1690 (1000)
Fine sand (150–400 μm)	1775 (1051)	845 (500)
Ground quartz (4 μm)	—	659 (390)
Silica fume (18 m ³ /g)	387 (229)	389 (230)
Precipitated silica (35 m ³ /g)	16.9 (10)	—
Superplasticizer (polyacrylate)	22.0 (13)	30.4 (18)
Steel fibers	323 (191)	1065 (630)
Total water	31.2 gal/yd ³ (153 L/m ³)	36.7 gal/yd ³ (180 L/m ³)
Cylinder compressive strength	24–33 (170–230)	71–99 (490–680)
Flexural strength	3.6–8.7 (25–60)	6.5–14.8 (45–102)
Fracture energy	15,000–40,000 J/m ³	1200–2000 J/m ³
Young's modulus	7.8–8.7 $\times 10^3$ (54–60 GPa)	9.8–10.9 $\times 10^3$ (65–75 GPa)

Note: 1 L/m³ = 0.2 gal/yd³ = 1.69 lb/yd³; 1 L (water) = 2.204 lb = 0.264 gal; 1000 psi = 6.895 MPa; 1 kg/m³ = 1.69 lb/yd³. Resistant type V cement was used in all the mixtures.

- Increase in the density of concrete by maintaining the fresh concrete under pressure at the placement stage and during setting, which results in the removal of air bubbles, expulsion of excess water, and partial reduction of the plastic shrinkage during final set
- Improvement in microstructure by hot curing for 2 days at 194°F (90°C) to speed the activation of the pozzolanic reaction of the silica fume, resulting in a 30% gain in compressive strength
- Increase in ductile behavior through the addition of an adequate volume fraction of steel microfibers.

Table 22.4 gives the mix proportions for Type 200 and Type 800 RPC concretes. It also lists the major mechanical properties of these concretes.

22.7 Prestressed Concrete Prism Elements as the Main Composite Reinforcement in Concrete Beams

Composite concrete that uses precast pretensioned prisms as its main tension reinforcement has shown promise for the effective control of cracking and deflection in structural concrete elements, particularly in the negative moment regions of reinforced concrete bridge decks. Most of the earlier studies on this subject were limited to experimental laboratory work (Chen and Nawy, 1994). Introducing highly precompressed prisms as the main reinforcement in the beam tension zone can increase ductility, control and delay the formation and propagation of cracking, reduce deflection, and improve the high-performance characteristics of environmentally exposed structural components, as reported by Chen and Nawy (1994). Their work involved several patterns of composite beams and a concrete strength of 14,000 psi (97 MPa), as shown in Figure 22.15. All evaluations were based on test-to-failure results. Fiberoptic Bragg grating sensors developed for this work were used to monitor strains, deformations, and crack widths in the 10-ft (3.3-m) simple, continuous beams that were tested. The relative mild steel and prestressed prism contents of the beams affected the behavior of these composite members (Chen and Nawy, 1994; Nawy and Chen, 1997). To account for this influence, a combined reinforcement index (ω) was used in the design of a prism-reinforced structural concrete beam. This index value was obtained from the following expression:

$$\omega = \frac{A_{ps}f_{ps} + A_s m f_y - A'_s f'_y}{b d_p f'_c} \quad (22.13)$$

FIGURE 22.15 Prism composite reinforcement geometry. (From Nawy, E.G. and Chen, B., in *Proceedings, Transportation Research Board*. National Research Council, Washington, D.C., 1998.)

where A_{ps} , A_s , and A'_s are the areas of prestressing and nonprestressing reinforcement, f_{ps} is the design stress in the prestressing reinforcement at ultimate load, f_y and f'_y are the yield strengths of deformed bars in tension and in compression, b is the width of the compression face of the member or flange in the case of a T-section, and d_p is the effective depth of the beam cross-section.

Other systems of composites can also improve the performance of reinforced concrete beams through the use of two-layer systems, one of which is made out of normal- or high-strength concrete and the layer above or below is made of high-strength polymer concrete. In such cases, the beam cross-section is built in two layers, in a manner similar to that of the SIFCON two-layer system. Several investigations have demonstrated that the shear friction interaction of the interface between the two layers of different strength concretes, one of which is a polymer concrete, has a resistance to slip superior to the interlock between two layers made from concrete only (Nawy et al., 1992).

Part B. Fiber-Reinforced Plastic (FRP) Composites

22.8 Historical Development

Use of nonmetallic fibers, particularly fiberglass elements, bundled into continuous reinforcing elements has been considered since the 1950s for prestressing reinforcement (ACI Committee 440, 1996; Nawy, 1996; Rubinsky and Rubinsky, 1954). Advances were made in polymer development by using polymer-impregnated bundled fiberglass fibers as rods for anchorages in tunneling. In the mid-1960s, Nawy et al. (ACI Committee 440, 1996; Nawy and Neuwerth, 1977; Nawy et al., 1971) conducted extensive work on the use of bundled and resin-impregnated glass fibers formed into deformed bars as the main

reinforcement in structural elements. Except for cases where magnetic fields in supporting structures had to be avoided, commercial application of bundled and resin-impregnated reinforcement in structural concrete elements was not recognized until the late 1970s. It is important to state at this juncture that the term *plastic* could be misleading; hence, there is general consensus at this time to define FRP as *fiber-reinforced polymer* composites.

In the 1980s, an increased interest in and use of such glass-fiber-reinforced polymer (GFRP) reinforcing bars was developing. This was particularly overdue and important for reinforced concrete surrounding or supporting magnetic resonance imaging (MRI) medical equipment. Such equipment includes sensitive magnets and cannot tolerate the presence of any steel reinforcement. Also, where environmental and chemical attacks are present, GFRP reinforcement is more durable and efficient as concrete reinforcement. As stated in ACI Committee 440 (1996), composite rebars have more recently been used in the construction of seawalls, industrial roof decks, base pads for electrical and reactor equipment, and concrete floor slabs in aggressive chemical environments. In 1986, Germany built the world's first highway bridge using composite reinforcement (ACI Committee 440, 1996).

In the United States, significant funds have been expended on product evaluation and further development, and at least nine major companies have been actively marketing this product since the early 1990s. Additionally, considerable progress has been made in using glass fiber filaments as a supplement to concrete matrices to improve the mechanical properties of concrete, but not as a replacement for the main bar reinforcement in supporting structural components. Glass fibers that are alkali resistant are also gaining wide use. These normally contain zirconium (ZrO_2) to minimize or eliminate the alkaline corrosive attack on glass present in the cement paste.

Synthetic fibers made from nylon or polypropylene, both loose and woven into geotextile form, have recently begun to be utilized due to the availability of information on their mechanical performance in the matrix and a better understanding of their structural contribution to crack resistance. Although the use of other types of nonmetallic fibers has been explored, interest has grown primarily in the use of carbon fibers as the main reinforcement apart from its use in cement-based composites. It is safe to state now that the science of fibrous concrete and composites has advanced to an extent that justifies its extended use in the years to come.

22.9 Beams and Two-Way Slabs Reinforced with GFRP Bars

In the late 1960s and early 1970s, Nawy and his team at Rutgers University (Nawy and Neuwerth, 1977; Nawy et al., 1971) researched the use of glass-fiber-reinforced plastic bars as a substitute for mild steel reinforcement. Those investigations involved testing to failure a total of 30 beams and 12 two-way slabs. The slabs had an average thickness of 2-1/2 in. and an overall dimension of 7×7 ft. The slab panels had 5.5×5.5 -ft effective spans and were fully restrained along all four boundaries. The GFRP reinforcement was spaced at 3 to 8 in. In the various slabs the reinforcement area varied from 0.196 in.²/ft to 0.074 in.²/ft in each direction, giving reinforcement percentages of 0.769% and 0.290%, respectively. The beams were either simply supported or continuous over two spans. The centerline span was 9 ft, 11 in. The reinforcement percentages in the beams ranged from 1.045 to 0.696%.

These original tests and analyses indicated that both the fiberglass-reinforced slabs and the beams behaved similarly in cracking, deflections, and ultimate load to steel-reinforced beams. The large number of well-distributed cracks in the GFRP-reinforced beams and slabs indicated that a good mechanical bond developed between the GFRP bar and the surrounding concrete. The research also demonstrated that the equations for flexure accurately predicted the flexural behavior of GFRP-reinforced members with the same accuracy as for the mild steel reinforced beams. A typical stress-strain diagram of the reinforcement is shown in Figure 22.16. This research led to investigations by Larralde et al., Satoh et al., Goodspeed et al., Ehsani et al., Zia et al., Bank and Xi, Porter et al., Faza and GangaRao, and Nanni (1993). A summary of their work and publications as well as details of the original Nawy (1971) work are given in the ACI Committee 440 report (1996). Table 22.5 provides a relative comparison of the mechanical properties of GFRP and steel reinforcement.

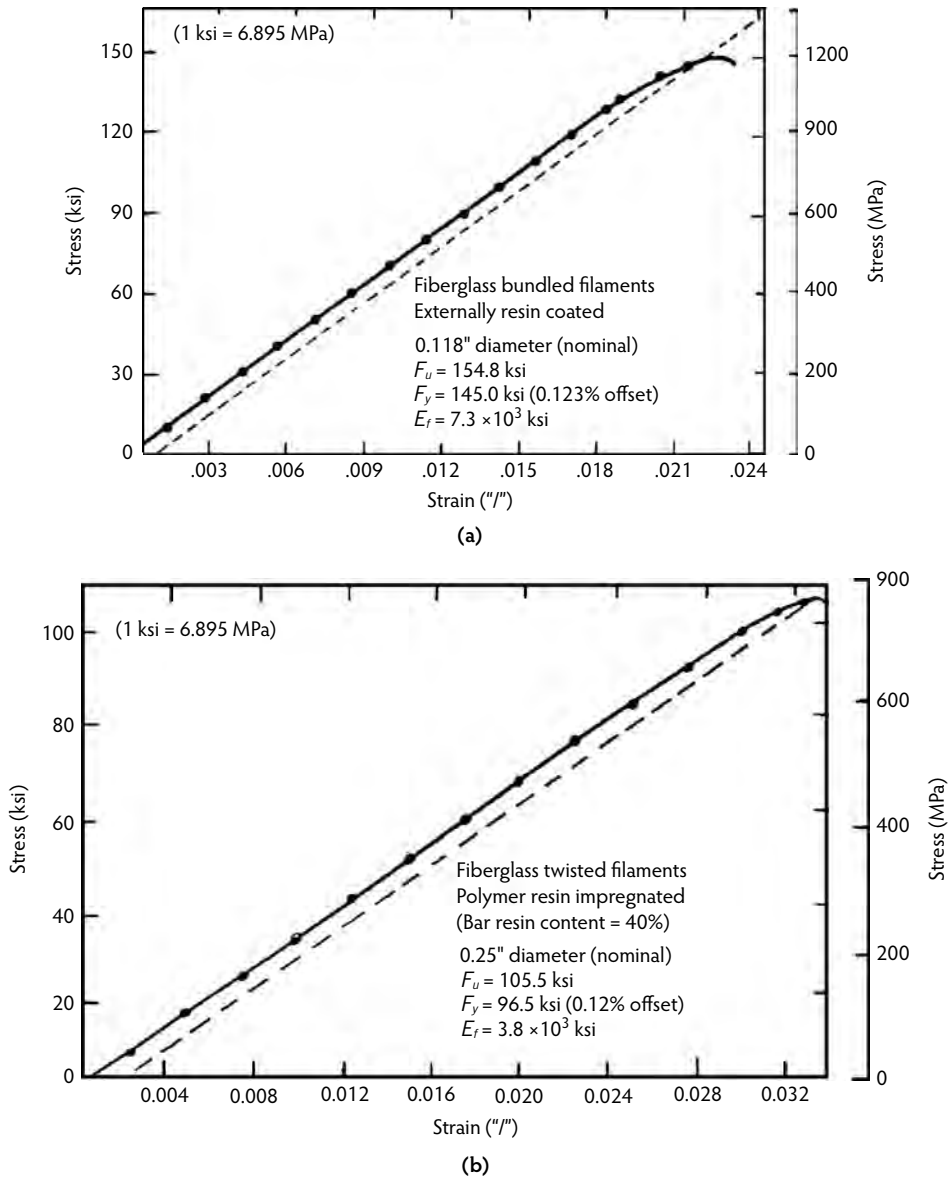

FIGURE 22.16 Typical stress-strain relationship of fiberglass composite bar reinforcement: (a) Coated filaments. (From Nawy, E.G. and Neuwerth, G.E., *Proc. ASCE J. Struct. Div.*, 103(ST2), 421–440, 1977.) (b) Impregnated filaments. (From Nawy, E.G. et al., *Proc. ASCE J. Struct. Div.*, 97(ST9), 2203–2215, 1971.)

22.10 Carbon Fibers and Composite Reinforcement

22.10.1 Carbon Fibers

Essentially, the two types of carbon fibers are high-modulus Type I and high-strength Type II. The fundamental difference between their properties is the result of the differences in their microstructures, which depend on the arrangement of the hexagonal graphine-layer networks in the graphite (ACI Committee 440, 1996). To attain a modulus of 30×10^6 psi (200 GPa), the graphine layers of high-modulus Type I carbon fibers are aligned approximately parallel to the axis of the fibers. Examples are

TABLE 22.5 Comparison of Mechanical Properties of GFRP and Steel Reinforcement

Kevlar® 49 by DuPont and Twaron® 1055 by Akzo Nobel. Ultra-high-modulus-fiber Kevlar® 149 and Twaron® 2000 are also available. Table 22.6 lists the minimum average strength values of Kevlar® and Twaron® reinforcing fibers. Additionally, hybrid composites made from carbon–glass–polyester are available with a strength of up to 115,000 psi (790 MPa), a modulus of 18×10^6 psi (124 MPa), and a density in the range of 0.060 to 0.069 lb/in³. It is important to state that, because of the low ductility of carbon fiber in comparison with steel, it is unlikely that it would be used as composite main bar reinforcement. Economically, it would be cost prohibitive; however, it can be used and is being used as prestressing reinforcement and as fabric reinforcement because of its high strength and high modulus, as seen in Table 22.6.

22.10.2 Hybrid GFRP and CFRP Reinforcement for Bridges and Other Structural Systems

Fiber-reinforced plastics have become widely popular in Japan, where it was originally initiated, as well as in the United States and elsewhere. They have been utilized in such transportation structures as bridge decks and in column encasements in earthquake retrofit construction, particularly hybrid GFRP bars. Figure 22.17 shows essentially negligible deflection at service load, even up to the ultimate load, with the

(From Nawy, E.G., *Concrete: The Sustainable Infrastructure Material for the 21st Century*, Circular E-C103, Transportation Research Board, Washington, D.C., 2006, pp. 1–24. Courtesy of Dr. A. Nanni.)

reserve deflection control capacity being almost twice that at the theoretical ultimate load. Figure 22.18 shows the deck of the hybrid GFRP-reinforced bridge deck in Bettendorf, Iowa, as an example. Figure 22.19 shows the use of this reinforcing system in beams in the super structure of a typical parking garage. Laminates of carbon-fiber-reinforced polymer (CFRP) can also be effectively used for mounting or wrapping concrete elements, such as damaged beam surfaces. Also, CFRP resin-impregnated strands can be spirally wound onto the surface of an existing concrete element, such as a bridge pier or structural building column. Due to the confinement imposed on the member, shear capacity and ductility are improved. CFRP plates are mounted on deteriorated surfaces using high bonding epoxies (Nawy, 2001). Table 22.7 lists the common properties of strengthening laminates. Such innovations can eliminate problems with durability and reinforcement corrosion that often plague bridge structures, garages, and deteriorated beam and slab elements in buildings.

TABLE 22.7 Properties of Strengthening Laminates

Property	Strengthening System				
	I	II	III	IV	V
Type of fibers	CFRP	CFRP	GFRP	GFRP	CFRP

22.10.3 Use as Internal Prestressing Reinforcement

Fiber-reinforced-plastic carbon tendons made with fiber elements 0.125 to 0.157 in. (3 to 4 mm) in diameter are used for prestressing. Their ultimate strength is comparable to prestressing strands, ranging between 270,000 and 300,000 psi (1866 and 2070 MPa).

22.10.4 Use as External Reinforcement

Unidirectional FRP sheets made of carbon (CFRP) or glass fiber (GFRP) bonded with polymer matrix (epoxy, polyester, vinyl, or ester) are being used to provide protection against corrosion, and they eliminate the need for joints because of the unlimited length of the composite sheets (ACI Committee 440, 1996). They are useful in increasing the flexural and shear strength of concrete members when these composite plates are epoxy bonded to the exterior facing of the elements. They are also of particular use in the retrofit of deteriorating concrete structures and in retrofitting columns in seismic zones. Several techniques for wrapping concrete elements with CFRP sheets have been developed (ACI Committee 440, 1996; Nanni, 1993). CFRP resin-impregnated strands can be spirally wound onto the surface of an existing concrete element such as a bridge pier or a structural building column. In this manner, due to the confinement imposed on the member, shear capacity and ductility are improved. Nanni's (1993) work on the effect of wrapping conventional concrete demonstrated that significant enhancement can be achieved in the strength and ductility of the wrapped concrete element.

22.11 Fire Resistance

The resistance of fiber-reinforced polymer composites is relatively lower than that of other systems, as degradation of the polymer resin content under heat and ultraviolet light can lead to some long-term durability problems. The carbon and glass fibers and the fabrics used in the FRP can withstand normal fire exposure and are durable under ultraviolet light, but the weak link is the organic polymers used to prepare the fiberglass or carbon used as reinforcing elements through impregnation or wrapping. One way to address this deficiency is to substitute an inorganic resin for the organic polymer (Foden et al., 1996). An inorganic resin can be an alkali aluminosilicate that can set at moderate temperatures and be able to withstand up to 1000°C. The system is highly impermeable so it can protect the carbon filaments from oxidation. Tests conducted on carbon, silicon carbide, and glass composites under tension, bending, shear, and fatigue loading indicated that the mechanical properties of the nonorganic composites used are comparable to those of organic polymer composites while having the advantage of relatively higher fire resistance (Foden et al., 1996).

22.12 Summary

The concretes described in this chapter have demonstrated that the strength, ductility, and performance of concretes and cement-based composites have and will continue to achieve higher plateaus. A new era in construction materials technology has commenced that promises to have a revolutionary impact on constructed systems in the 21st century. Considerable work must be done to enhance the practicability of these materials and make them cost effective. It is only with simplicity and practicability in application and the achievement of a cost-effective competitive end product that these developments in the science of materials technology can gain universal acceptance and large-scale application.

23.1 Introduction

Overlays are usually placed on bridge decks to reduce the infiltration of water and chloride ions and to improve the skid resistance, ride quality, drainage, and appearance of the surface. The protection provided by the overlay can extend the life of the deck. Three types are typically used: asphalt overlays on membranes, polymer concrete overlays, and hydraulic cement concrete (HCC) overlays. Asphalt overlays on membranes and polymer overlays have been successfully used on decks that are in good condition but require a skid-resistant surface and protection against chloride intrusion (AASHTO, 1995b; NCHRP, 1995). HCC overlays have been used successfully on similar decks, as well as on decks that require a significant amount of concrete removal and rehabilitation. Overlays are placed on pavements to increase the stiffness and to improve the skid resistance, ride quality, drainage, and appearance of the surface. Both asphalt and concrete overlays are used on both asphalt and concrete pavements. HCC pavement overlays that are thicker than 4 in. are typically unbonded, and HCC overlays that are ≤ 4 in. thick are typically bonded. The overlays can extend the life of pavements. This chapter deals only with bonded HCC overlays placed on concrete bridge decks and concrete pavements; however, the designs, specifications, materials, and construction techniques should be applicable to concrete decks in buildings, parking garages, and similar concrete structures.

* Associate Director, Virginia Transportation Research Council, Charlottesville, Virginia, and Section Head, Transportation Research Board; expert in materials and construction, particularly public works.

23.2 Key Issues for Successful Bonded HCC Overlays

Properly constructed, HCC overlays can last 30 years or more. Although effective long-lasting overlays have been constructed, some overlays have cracked and delaminated and have had to be replaced before the bridge was opened to traffic. Key issues for long-lasting overlays are the contractor performance, material properties, bond strength, thickness, surface characteristics, and protection characteristics of the overlay. Many failures have been caused by placing too much emphasis on material compressive strength and protection properties and too little emphasis on the other, typically more important properties. Factors that often contribute to premature delamination of the overlay include poor surface preparation, use of mixture proportions with high shrinkage, and early shrinkage cracking in the overlay. Some other factors include the use of construction joints, use of thick overlays, and creep and shrinkage of newly constructed superstructures. Design, specification, material, and construction requirements and construction procedures that can be used to provide long-lasting HCC overlays follow.

23.2.1 Contractor Performance

Overlays are difficult to construct. Obtaining and maintaining the high bond strengths for long-lasting overlays requires that appropriate construction decisions be made with respect to the selection and use of concrete removal and surface preparation equipment and procedures, mixture proportions, and placement and curing procedures. A properly equipped and experienced overlay contractor is more likely to perform well and less likely to have problems with the construction. Use of performance-based end-result specifications in which the contractor is rewarded for the quality of the final product rather than being compensated for following a prescription specification encourages good performance.

23.2.2 Overlay Material Properties

23.2.2.1 Overlay Mixture Proportions

Materials that have been successfully used for bridge deck overlays include Type I/II Portland cement with 15% styrene-butadiene latex by weight of cement, referred to as *latex-modified concrete* (LMC); low water/cement ratio hydraulic cement concrete mixtures; and Portland cement mixtures in which silica fume (SF), fly ash, or slag is substituted for a portion of the Portland cement (Sprinkel, 1984, 1992b; Sprinkel and Ozyildirim, 1999b; Tyson and Sprinkel, 1975).

For situations in which traffic must be placed on the overlay after a curing time of 24 hours or less, successful overlays include LMC constructed with Type III Portland cement (LMC-HE), Type II Portland cement and 7% silica fume, and LMC overlays constructed with calcium sulfoaluminate and dicalcium silicate cement, referred to as *LMC very early strength* (LMC-VE) overlays. Traffic can be placed on the LMC-VE overlays after only 3 hours of curing at concrete curing temperatures of 50°F and above (Sprinkel, 1998b, 1999). At temperatures of 80°F and above, a citric acid admixture must be added to retard the mixture. Typical mixture proportions are shown in Table 23.1 (Sprinkel, 1988, 1998b, 2001;

TABLE 23.1 Typical Mixture Proportions

Mixture	LMC	Silica Fume	Fly Ash	Slag	LMC-HE	LMC-VE

Age	LMC (psi)	Silica Fume (psi)	Fly Ash (psi)	Slag (psi)	LMC-HE (psi)	LMC-VE (psi)
3 hours	—	—	—	—	—	3510
4 hours	—	—	—	—	—	3810
5 hours	—	—	—	—	—	4070
24 hours	1810	2960	3100	3400	3750	5440
7 days	3360	5140	5050	5330	5280	6290
28 days	4630	6980	6820	7180	6340	6710

Sprinkel and Moen, 1999; Sprinkel and Ozyildirim, 1999b). The latex admixture is typically a 48% solids solution that is added to the mixture at the dosage of 3.5 gallons per bag of cement. High-range water-reducing (HRWR) admixtures (ASTM, 2008) are typically added to mixtures with silica fume to help disperse the silica fume and to provide the desired workability. Air-entraining admixtures are used with all but the LMC mixtures. The latex tends to provide air voids in LMC mixtures, and an air-detaining admixture has to be added when the air content is too high.

Aggregates used in overlays typically meet the requirements of ASTM C 33 (ASTM, 2007) and the coarse aggregate is typically a No. 7 or No. 8. The LMC is batched and mixed at the point of discharge using calibrated mobile concrete mix trucks. The trucks have compartments in which the ingredients are stored separately until conveyed to a mixer on the back of the truck. Other mixtures are typically batched at a ready-mix plant and delivered to the discharge point in ready-mix trucks. Although the overlay mixtures in Table 23.1 can be used on pavements, typically the less costly mixtures are used. These include Portland cement concrete with fly ash or slag (Sprinkel and Ozyildirim, 1999a). Even the less costly mixtures are more expensive than asphalt overlays on pavements; however, in some situations, because of rutting of available asphalt mixtures, structural requirements for the composite pavement, and the availability of suitable asphalt and concrete paving materials and paving contractors, bonded concrete overlays can be economical on a life-cycle cost basis.

23.2.2.2 Compressive Strength

Overlay mixtures are typically specified to meet a minimum compressive strength (ASTM, 2005). A typical minimum compressive strength for opening an overlay to traffic is 3000 psi. Other values have been ranging from 2500 to 5000 psi depending on the requirements for the deck and the overlay mixture (VDOT, 2002). The minimum compressive strength provides an indication that acceptable concrete was provided. More importantly, it provides an indication that the overlay can have acceptable bond strength when opened to traffic. Bond strength is discussed in more detail later. Compressive strength data for typical overlay mixtures described in Table 23.1 are shown in Table 23.2 (Sprinkel, 1988, 1998b; Sprinkel and Moen, 1999; Sprinkel and Ozyildirim, 1999b). The 4-in.-diameter by 8-in.-long cylinders were typically moist cured prior to testing, with the exception that LMC specimens were typically air cured in the lab after 2 days of moist curing. The numbers are average values obtained from several deck overlay projects.

23.2.2.3 Permeability

In recent years overlay mixtures have been specified to meet a maximum permeability (AASHTO, 1995b). The maximum permeability provides an indication that the overlay will be resistant to the penetration of chloride ions and therefore can protect the reinforcing steel in the deck from corrosion for the life of the overlay. The maximum permeability is typically 1500 coulombs (C) at 28 days. Other values have been specified, ranging from 1000 to 2000 C at 28 days. Because the permeability typically decreases with age and because the early age permeability is affected by the ingredients and curing conditions, the permeability at 28 days of age does not typically provide a good indication of the permeability at later age. A procedure that accelerates the curing of the specimens by storing them at 100°F is being used to provide a better indication of later age permeability using 28-day test results (VDOT, 2006). Permeability is discussed in more detail in the section on protection.

TABLE 23.3 Permeability (AASHTO T277)

Age	LMC (C)	Silica Fume (C)	Fly Ash (C)	Slag (C)	LMC-HE (C)	LMC-VE (C)
28 days	1500–2560	950–2330	1000–1160	1040–1390	1320–2850	300–1400
1 year	200–2060	590–1280	290–300	570–820	320–1280	0–10
3 year	300–710	520–1460	300–360	500–590	—	—
5 year	450–500	780–910	—	—	510	—
9 year	100–400	—	—	—	—	0–60

Permeability data for typical overlay mixtures described in Table 23.1 are shown in Table 23.3 (Sprinkel, 1988, 1998b, 2000; Sprinkel and Moen, 1999; Sprinkel and Ozyildirim, 1999b, 2000b). The data are typically based on tests of 4-in.-diameter by 2-in.-thick slices cut from the tops of cores taken from the overlays. The numbers are maximum and minimum values obtained from several deck overlay projects. The range is often large because the overlay thickness and overlay ingredients varied from project to project. Some projects had 2-in.-thick overlays, and others had 1.5- to 2-in.-thick overlays, so as much as 0.5 in. of the bottom of the slice could be deck concrete with a higher permeability. A permeability of <100 C is negligible, 100 to <1000 C is very low, and 1000 to 2000 C is low (AASHTO, 1995). Whereas the permeability at 28 days is typically low for the mixtures, over time the permeability generally drops to the very low range. The permeability of the LMC-VE mixture drops to the negligible range over time.

23.2.2.4 Shrinkage

In the years ahead, it is anticipated that overlay materials will be required to meet a maximum shrinkage requirement to minimize or help eliminate cracks in overlays. Cracks are typically caused by a combination of factors that include plastic, autogenous, and drying shrinkage. To minimize cracks in overlays caused by autogenous shrinkage and drying shrinkage, a maximum length change after 28 days of drying of less than 0.04% is a desirable goal. To account for autogenous shrinkage, the test procedure must be

FIGURE 23.1 Length change of four LMC mixtures. (From Sprinkel, M.M., *Latex-Modified Concrete Overlay Containing Type K Cement*, VTRC 05-R26, Virginia Transportation Research Council, Charlottesville, 2005.)

modified to include an initial measurement at the time the concrete sets rather than at 24 hours of age as specified by ASTM C 157 (ASTM, 2006). Figure 23.1 shows the length change of four LMC mixtures (Sprinkel, 2005): LMC, LMC-HE, LMC-VE, and LMC mixtures made with Type K expansive cement (ASTM, 2004b). Six specimens were made from each of the four mixtures. Three specimens from each mixture were moist cured for 28 days (wet cure), and three were wet cured for the typical 2-day period and allowed to dry in the air in the laboratory after 2 days (dry cure). Each curve in Figure 23.1 is based on the average of the measurements on three specimens, 3 × 3-in. by 11 in. long. The curves indicate that the LMC and LMC-HE mixtures have a 28-day drying length change of approximately 0.04%, and the long-term length change is approximately 0.08%. Some overlays made with these mixtures have few cracks, but these mixtures are prone to plastic shrinkage cracking, and drying shrinkage causes the cracks to be wider. The curves indicate that the LMC-VE and LMC Type K cement mixtures have less length change than the LMC and LMC-HE mixtures and should be less prone to cracking. Specimens from the LMC Type K cement mixture that were moist cured for 28 days showed a significant increase in length. This increase could cause the overlay to delaminate from expansion rather than from shrinkage; however, because LMC overlays are typically moist cured for 2 days, excessive expansion typically should not be a problem. Shrinkage is discussed in more detail in the section on protection.

23.2.3 Overlay Bond Strength

The service life of an overlay is usually controlled by a failure in the vicinity of the bond interface between the overlay and the deck. The failure may be at the bond interface, in the base concrete just below the bond interface, in the overlay just above the bond interface, or at a combination of these failure locations. For convenience, unless otherwise indicated, a failure in the vicinity of the bond interface will be referred to as a *bond failure*. Factors that contribute to high bond strength include the following:

- The deck concrete is in good condition.
- Surface damage from concrete removal from the deck surface is minimal.
- Deck preparation provides a sound, clean, textured and damp surface.
- Overlay concrete is properly consolidated and cured.

Bond strength is a function of the strength of the deck concrete, surface preparation, placement of the overlay concrete, curing of the overlay concrete, and the strength of the overlay concrete. Overlay bond strength cannot be higher than the strength of the concrete in the deck and overlay.

23.2.3.1 Deck Concrete Is in Good Condition

Factors that provide an indication that the deck concrete is in good condition include the following:

- The concrete has adequate strength and few cracks.
- The reinforcement is not corroding.
- The concrete is properly air entrained and not deteriorating from alkali-silica reaction, freeze-thaw action, or other progressing material distress.

Properly prepared 4000-lb/in.² compressive strength concrete surfaces can provide tensile bond strengths of approximately 280 lb/in.² (Sprinkel, 2003b). Most overlays will have a compressive strength that exceeds 4000 lb/in.² which is more than adequate for most situations. Cracks in the deck will typically reflect through the overlay and may cause a reduction in bond strength in the vicinity of the crack. The exception can be dormant shrinkage cracks that are not moving and may not reflect. Corroding reinforcement can cause cracks in the concrete around the reinforcement and will eventually cause a reduction in bond strength. Concrete that is salt contaminated or failing because of distress from freezing and thawing or alkali-silica reaction should be removed prior to placing an overlay. Overlays should not be used to cover concrete that should be removed.

TABLE 23.4 Concrete Removal Options and Practical Removal Depths

Concrete Removal Option	Practical Removal Depth
Grit blast	<2 mm
Shot blast	<6 mm
Diamond grind	<Rebar depth
Scarification (milling)	<Rebar depth
Hydro demolition	1 mm to half depth
Pneumatic hammers	12 mm to full depth

23.2.3.2 Minimal Damage from Concrete Removal

Overlay construction typically begins with the removal of chloride-contaminated concrete and other deteriorated concrete from the deck. The depth of removal depends on the depth of deterioration and typically varies across the deck. Removal may range from as little as surface texturing to as much as full-depth removal. Deep areas should be patched prior to placing the overlay, although on occasion small areas are sometimes patched as the overlay is placed. In some situations, particularly new decks, it is not necessary to remove a considerable depth of concrete, as simple surface cleaning can provide adequate bond strengths. Concrete can be removed to greater depths to improve the grade or surface profile prior to placing the overlay or to allow for a thicker overlay to be placed. On older bridge decks, concrete may be deteriorated to the point where major concrete removal is required. Concrete removal options and typical removal depths are shown in Table 23.4. In situations in which surface cleaning and texturing are all that is required, the preferred methods are grit blast, shot blast (Figure 23.2), and hydro demolition. When concrete must be removed to greater depths, the grit blast and shot blast methods are not practical. Scarification works well to remove concrete to just above the rebar but care must be exercised not to hit the rebar. Also, follow-up removal by grit blast, shot blast, or hydro demolition is recommended to remove fractured concrete. Fine milling heads, as shown in Figure 23.3, are being used to minimize damage to the milled surface. Hydro demolition can be used to remove concrete around reinforcing steel as shown in Figure 23.4. When reinforcement is exposed, concrete removal should continue to a depth that is at least 1 in. below the reinforcement so the bond interface is not located in the reinforcement. Scarification followed by hydro demolition works well for removing the top half of the deck. The hydro demolition equipment abrades the deck surface with water at nozzle pressures that are typically about 26,000 lb/in.². The cuttings and water are usually collected and vacuumed from the surface. Large self-contained units are used for applications ranging from surface texturing to full depth removal of concrete. Large pneumatic hammers are practical for full-depth removal. A variety of methods may be used to remove deteriorated concrete. Impact methods such as hammers and scarification may fracture the concrete left in place, whereas hydro demolition does not. When impact methods are used, additional removal with other methods should be done to remove damaged and fractured concrete. Following concrete removal and patching the surface must be cleaned and textured to get good bond strengths (Sprinkel, 1997).

23.2.3.3 Surface Preparation Provides a Sound, Clean, Textured, and Damp Surface

A specification that, when enforced, should provide a properly prepared surface states: "Clean surface by shot blasting and other approved cleaning practices to remove asphalt, oils, dirt, rubber, curing compounds, paint, carbonation, laitance, weak surface mortar, and other detrimental materials that may interfere with the bonding or curing of the overlay" (VDOT, 2001). Techniques that can be used typically include a combination of the following: grit blast, shot blast, hydro demolition, power washing, and air blast. The quality of a grit blast depends on the skill of the person doing the blasting and the time devoted to the effort. Shot blasting, as shown in Figure 23.2, is a more mechanized way to prepare concrete surfaces to achieve high bond strengths. The shot blaster abrades the deck surface with shot and vacuums up the shot and concrete cuttings. The shot does not leave fractures in the prepared concrete surface. By monitoring the speed and number of passes of the shot blaster, proper surface preparation can be

FIGURE 23.2 Shot blast provides for good bond strength by cleaning and texturing the concrete surface.

FIGURE 23.3 Fine milling heads spaced ≤ 8 mm apart as shown are being used to minimize damage to the milled surface.

FIGURE 23.4 Hydro demolition can be used to remove concrete around reinforcing steel.

FIGURE 23.5 Metal disks or plates are bonded to the surface and pulled in tension.

achieved. The shot blaster typically removes up to 1/8 in. of the surface, and larger shot blasters can remove up to 1/4 in. of the surface. Hydro demolition equipment can also be used to prepare concrete surfaces to achieve high bond strengths. A low-pressure water blast is used for the final cleaning of the surface prior to placing the concrete overlay. The saturated concrete deck that results from the hydro blasting provides for a good cure of the overlay concrete.

When it may not be clear what is required for acceptable surface preparation, the test method prescribed in ACI 503R (ACI Committee 503, 1993) or ASTM C 1583 (ASTM, 2004a) can be used to determine the cleaning and texturing practice necessary to provide a tensile bond strength in test patches or a tensile surface strength in prepared surfaces greater than or equal to some minimum value (AASHTO, 1995b; ACI Committee 503, 1993; ASTM, 2004a; Sprinkel, 1997). A minimum value of 250 psi has been used (VDOT, 2001). A lower quality limit of 150 psi was used in a performance specification in which the contractor was paid for the percent of tests that were within the specification limits (Sprinkel, 2004b). A bond strength test result is usually based on the average of three individual tests. A failure at a depth of 0.25 in. or more into the base concrete is preferred (AASHTO, 1995b; VDOT, 2001).

As shown in Figure 23.5, metal disks or plates can be bonded to the prepared surface and pulled in tension to provide an indication of the tensile strength of the prepared surface. A rapid-setting acrylic adhesive can be used to bond the test disks or plates to the surface. The advantage of testing the prepared surface is that results are obtained in approximately an hour, and surface preparation activities can be adjusted as needed with negligible delay to the project. The disadvantage is that the bond strength of the HCC overlay is likely to be less than that of the acrylic adhesive used to bond the disks or plates. Also, bond problems resulting from the overlay mixture and placement are not identified ahead of time (Sprinkel, 2003b).

As shown in Figure 23.6, on larger jobs it may be practical to construct HCC overlay test patches with one or more overlay mixtures and different surface preparation procedures. Overlay mixtures and surface preparation procedures that give the desired results can be specified. Although days or weeks may be required for the overlay concrete to cure sufficiently to get tensile bond strength test results, any problems associated with the deck concrete, surface preparation, and placement and curing of the overlay can be identified ahead of time and appropriate adjustments made prior to placing the overlay. On very large jobs and where time permits, a full-width bridge deck section can be placed and tested with the concrete mixture and procedures that gave good results for the test patch.

When the acceptable cleaning and texturing practice has been determined, it is necessary to ensure that the practice is carried out over the entire deck surface. This is accomplished by determining the macro texture of the prepared surfaces upon which the acceptable bond tests were done (the macro

FIGURE 23.6 An overlay test patch is tested for bond strength.

FIGURE 23.7 Macrotexture depth measurement to ensure surface preparation (ASTM E 965).

texture is usually determined prior to construction of the test patches or test sections) and monitoring the macro texture of the prepared deck surface to ensure that the surface macro texture is the same or heavier than that on which the bond tests were performed (Sprinkel, 1997).

Two methods can be used to monitor the macro texture of the prepared deck surface (Sprinkel, 1997, 1998a). As shown in Figure 23.7, a quantitative macro texture result for the prepared surface can be determined by measuring the macro texture using the procedure specified in ASTM E 965 (ASTM, 1996). A qualitative indication of the macro texture of the prepared surface can be determined by using the International Concrete Repair Institute (ICRI) molded standards shown in Figure 23.8 (ICRI, 1997). The texture of the prepared surface is compared to the texture of the ICRI molded standard determined to best represent the prepared surface upon which acceptable bond tests were determined. A result for the macro texture measurement is based on the average of ten sand patch tests. Use of the ICRI nine molded standards requires less effort, but the owner and contractor must be able to agree on the qualitative assessment. Recent research indicates a strong correlation between laser surface macro texture measurements and the ASTM E 965 procedure (Stroup-Gardiner and Brown, 2000). Laser measurements to monitor surface preparation are a third option that will likely see greater use in the future.

Minimum macro texture values based on ASTM E 965 that have been specified in contracts include 0.06 in. and 0.08 in. (Sprinkel, 1997; Sprinkel and Ozyildirim, 1999b). Whereas 0.06 in. is often an acceptable minimum value, more or less cleaning may be required to obtain high bond strengths. Typically more cleaning and therefore texturing are necessary for old concrete surfaces than for new

FIGURE 23.8 ICRI molded standards ensure proper surface preparation. (From ICRI, *Selecting and Specifying Concrete Surface Preparation for Sealers, Coatings, and Polymer Overlays*, Guideline No. 03732, International Concrete Repair Institute, Sterling, VA, 1997.)

ones. Also, the type and size of the aggregates in the deck can affect the optimum minimum texture value. For the same blasting effort, decks with lightweight aggregates will typically have a higher texture than decks with hard, dense aggregates because the aggregates abrade away in the lightweight decks and the mortar abrades away in the decks with hard aggregate. The minimum texture that provides good bond strength will depend on the materials in the deck, the condition of the deck, and the cleaning technique used.

As the surface is prepared, the screed is set to the proper elevation. A trial run of the screed is made with a spacer block attached to the bottom of the screed to ensure that proper cover between the screed and top reinforcement and the required minimum overlay thickness are obtained. After the screed is set and cleaning and texturing of the surface are complete, the prepared surface is wetted with potable water and covered with a polyethylene sheet to protect the prepared surface until the sheet is removed minutes prior to placing the overlay concrete. Any contamination of the prepared surface prior to placing the overlay must be removed, and dry surfaces should be rewetted so the surface is damp but has no standing water where the overlay concrete is being placed.

23.2.3.4 Overlay Concrete Is Properly Placed and Consolidated

Figure 23.9 shows the typical concrete placement procedure which is as follows:

- Deposit the overlay concrete onto the prepared surface.
- Broom mortar from the overlay concrete onto the prepared surface, and discard the excess coarse aggregate from the mortar.
- Consolidate and strike-off the concrete using a screed that vibrates.
- Finish the surface using a float that is typically attached to the back of the screed.

Some hand-finishing is typically required along the edges of the placement. Proper consolidation of the concrete at the bond interface is required for high bond strength. The vibrating pan on the front of a screed, vibrating rollers, and a vibrating strike-off bar can consolidate overlays <2.5 in. thick. The frequency of vibration can be adjusted, and care should be taken to ensure that the screed is providing adequate consolidation. Surface vibration decreases with the distance from the surface and typically fails to properly consolidate the concrete at depths greater than approximately 2.5 in. Internal vibrators are used to consolidate areas that are deeper than 2.5 in.

FIGURE 23.9 Screed strikes off and consolidates the overlay concrete.

FIGURE 23.10 Wet burlap is placed on the overlay surface as soon as possible to prevent plastic shrinkage cracks.

Some recent experience indicates that, with proper consolidation of the overlay at the bond interface, the use of brooms to apply mortar from the overlay or from separate containers does not contribute to bond strength; therefore, this step can be eliminated. Moreover, it is a step that, when done incorrectly, can cause lower bond strengths. Incorrect applications include the mortar drying before the overlay concrete is placed, retempering of a separate container of bonding mortar that results in a low strength layer of mortar, or placement of bonding mortar on a prepared surface that has a texture so heavy that a thin and uniform layer of bonding mortar cannot be placed.

23.2.3.5 Overlay Concrete Is Properly Cured

The overlay concrete must be properly cured to achieve high bond strengths. The bond strength cannot be higher than the strength of the overlay concrete, and the strength of the overlay concrete is a function of the quality and completeness of the curing. As can be seen in Figure 23.10, from the time the overlay concrete is deposited on the prepared surface until the curing materials are applied, water evaporates from the surface of the overlay concrete. The evaporation rate can be estimated using a nomograph that

FIGURE 23.11 Polyethylene sheeting covers wet burlap for the curing period.

takes as input data the air temperature, relative humidity, concrete temperature, and wind speed. When evaporation rates are high, the contractor can take steps to reduce the rate. Special precautions are typically followed when evaporation rates exceed $0.1 \text{ lb/ft}^2/\text{hr}$. These include fogging the air over the surface of the overlay to increase the relative humidity, batching the concrete at a lower temperature, and installing wind breaks to reduce the wind speed over the surface of the overlay.

Regardless of the evaporation rate, the wet burlap curing material should be placed on the finished concrete surface as soon as possible to stop further evaporation and to prevent plastic shrinkage cracking. As shown in Figure 23.11, polyethylene is placed on the wet burlap as soon as practical to help keep the burlap wet. Soaker hoses can be placed under the polyethylene to maintain the burlap in a wet condition during the curing period. The burlap should not be allowed to dry, as dry burlap can remove water from the overlay that is necessary for curing. LMC is typically moist cured for 2 days and other HCC overlays for 3 to 7 days. Longer curing periods are beneficial for the quality of the concrete but often not practical because of the need to accelerate construction and to open the overlay to traffic. LMC-VE overlays are cured for 3 hours or until opened to traffic.

23.2.3.6 Minimal Full-Depth Cracks

Plastic shrinkage cracks can occur when water evaporates from the overlay concrete because there is no water on the surface to protect the concrete from evaporation. These cracks are often fine and shallow but typically become wider, as shown in Figure 23.12, because of drying shrinkage. The cracks can penetrate the full thickness of the overlay either initially or at a later age because of drying shrinkage. Shrinkage of the overlay can stress the bond interface because the overlay is trying to shorten relative to the deck. These stresses are the highest around the perimeter of the overlay, along construction joints, and along full-depth cracks in the overlay. These stresses can cause delamination of the overlay, and the area of delamination can increase with time. Although cracks compromise the protection provided by the overlay, cracks that are full depth can increase the risk of delamination of the overlay along the cracks. The overlay concrete must also be properly cured to help prevent full-depth cracks.

23.2.3.7 Joints

To accommodate traffic, overlays are often constructed one lane at a time with traffic in the adjacent lane which results in longitudinal construction joints. These joints are like full-depth cracks in the overlay and should be avoided because they can cause premature delamination of the overlay. When possible, overlays should be placed over the entire width and length of the deck span and without any joints. Joints often control the time to repair or replace properly constructed overlays. Bridge decks with more than

FIGURE 23.12 Shrinkage cracks are apparent in an overlay placed on a bridge deck.

one span may have expansion joints to allow for movement between the spans. The overlay should not be placed over the joints because the overlay will crack and delaminate along the joints. Joints must be constructed in the overlay directly above the joints in the deck. Typically, the joints in the overlay are similar to and replace the joints in the deck. In some situations, the construction of an overlay provides the opportunity to replace leaking joints with joints that will perform better. Either new joints or forms for new joints are placed directly above the joints in the deck, and the overlay concrete is placed against the joints or forms. When forms are used, they should be constructed with a compressible layer of material to minimize compression stresses in the overlay and shear stresses at the bond interface that may be caused by expansion of the adjacent deck spans. Also, the forms should be removed shortly after the concrete sets so the joint in the overlay can allow for movement between the adjacent deck spans (Sprinkel and Ozyildirim, 1999b). The open joint must be filled with a suitable joint material in accordance with recommended practice.

23.2.4 Overlay Thickness

Bonded concrete overlays for bridge decks are typically designed to have a nominal 1.5-in. thickness. The minimum thickness is 1.25 in., and the installed thickness typically ranges from 1.25 to 2 in. A mixture with No. 7 or No 8 coarse aggregate works well for these overlays. In situations in which the minimum thickness of the overlay is greater than 2 in., the typical overlay mixture should be redesigned to reduce shrinkage by increasing the maximum size of the coarse aggregate and if practical to reduce the cement materials content. The optimum concrete mixture has a maximum coarse aggregate size that is one third the minimum thickness; for example, No. 67 aggregate should be used in 2.25- to 3-in.-thick overlays, and No 57 aggregate should be used in 3- to 4-in.-thick overlays. Bonded concrete overlays are typically not designed to be thicker than 4 in., but thicker overlays are sometimes constructed to provide a suitable grade and profile for the surface. The thickness of an overlay is often varied over the deck surface to improve the drainage, surface profile or ride quality and to fill areas not patched prior to placing the overlay; however, the overlay is typically designed for the thinnest areas. When practical, the mixture should be changed to accommodate the thicker areas.

The thickness of an overlay is a factor in performance. Mortar rather than concrete is used for overlays that are thinner than 1.25 in. The mortar typically has higher shrinkage and therefore is more prone to cracking than concrete. The cracking can cause delamination of the overlay. Shrinkage of the overlay can stress the bond interface because the overlay is trying to shorten relative to the deck. The stress increases as the thickness of the overlay increases; therefore, overlays thicker than 2 in. are more prone to delamination. The stress can be reduced by changing the mixture to reduce shrinkage. Overlays have delaminated before being opened to traffic when a concrete mixture designed for a 1.5-in.-thick overlay was placed 4 in. thick. The optimum nominal thickness for a bonded concrete overlay is 1.5 in.

23.2.5 Overlay Surface Characteristics

Obtaining overlays with desirable surface characteristics, including good skid resistance, ride quality, drainage, and surface appearance, is typically not a problem. These factors are easily achieved with good design and construction practices. The overlay must be designed and the screed must be set to provide a final grade that provides for good ride quality and good drainage. The surface of the plastic concrete must be struck off and finished to the final grade shown on the plans. Good skid resistance is obtained by tining the plastic overlay concrete or by saw-cutting grooves into the hardened concrete surface. Tined valleys and saw-cut grooves are typically 1/8 in. wide, 1/8 in. deep and spaced 3/4 in. apart (VDOT, 2002).

23.2.6 Overlay Protection Characteristics

The protection provided by an overlay is a function of its thickness, permeability, diffusion constant, shrinkage, and cracks. Construction joints, like cracks, can affect the level of protection provided. The thicker the overlay, the greater the cover over the reinforcement and therefore the greater the protection provided. As mentioned earlier, however, overlays thicker than 2 in. are more likely to delaminate. Many HCC overlay mixtures can provide low permeability. Use of styrene–butadiene latex or supplemental cement materials, such as silica fume, fly ash, and slag, and good concreting practices easily provide for overlay concretes with a low permeability (<1000 C) (AASHTO, 1995b). Permeability values for typical overlays are shown in Table 23.3 (Sprinkel, 1988, 1998b, 2000; Sprinkel and Moen, 1999; Sprinkel and Ozyildirim, 1999b, 2000). The diffusion constant for the overlay concrete can be calculated using Fick's second law of diffusion. It provides an indication of the rate at which chloride moves through the overlay. The lower the constant, the longer it takes for chloride to penetrate the overlay. Concretes with a low permeability typically have a low diffusion constant.

Cracks compromise the protection provided by the overlay by allowing chlorides and water to bypass the low-permeability overlay concrete and travel directly to the reinforcement. Shrinkage can cause cracks in the overlay. The lower the shrinkage, the less prone the overlay is to cracking and delamination. Construction joints, like cracks, can allow for the penetration of chlorides. In addition to shrinkage, cracks can be caused by thermal contraction when overlay concrete is placed that has a much higher temperature than the deck. Cracks can be caused by cracks in the deck reflecting through the overlay, by superstructure creep and shrinkage when overlays are placed on newly constructed structures, and by traffic when the traffic loading causes tensile stress in the surface of the overlay. Most cracks in overlays originate as plastic shrinkage cracks and widen because of one or more of the other causes. Typically, a relatively crack-free overlay can be obtained when a low-shrinkage mixture is properly placed and protected from plastic shrinkage cracking.

Gravity-fill polymers can be placed in shrinkage cracks to help seal them. Products that have been successfully used include high-molecular-weight methacrylate, epoxy, and urethane (Sprinkel, 1992a, 1995). Typically the overlay surface is flooded with the monomer, and brooms are used to work the liquid into the cracks. Cracks that are not close enough to justify flooding the surface can be treated individually. Silane can also be used to seal cracks. The silane is easy to apply and makes the surface of the crack hydrophobic so it repels water. Although an overlay with sealed cracks cannot be expected to perform as well as an overlay with no cracks, application of the gravity-fill polymer or silane sealer is the only practical way to reduce the penetration of chlorides and water through the cracks.

Because the cracks will likely widen with age, it is best to wait as long as practical to seal them. The best time is a function of the shrinkage of the concrete and the use of the structure. Most of the shrinkage has occurred in approximately 3 months for a typical HCC overlay. The shrinkage may occur faster in the summer than in the winter. As much as approximately 25% additional shrinkage may occur after 3 months, so waiting 6 months to a year or more before sealing the cracks is desirable but often not practical. Another option is to seal the cracks once at an early age before opening the deck to traffic and again after 2 years after most shrinkage has occurred. Very early strength materials may be effectively sealed at an earlier age.

23.3 Other Issues

23.3.1 Rapid Construction of Overlays

In the past, most bridge decks and pavements were closed to traffic for the construction of an overlay. As traffic volumes have continued to increase, it has become difficult if not virtually impossible to close many structures for overlay construction. Overlays are typically placed one lane at a time with traffic in adjacent lanes. In the most heavily congested situations, lanes are only closed for short periods of time, such as weekends or nights, and short segments of overlay are placed during each lane closure. The sequence of construction steps for the construction of LMC-VE overlays follows:

Phase 1

- Close lane at 9 p.m.
- Mill deck surface.
- Patch deck.
- Cure patches.
- Open lane at 5 a.m.

Phase 2

- Close lane at 9 p.m.
- Shot blast surface.
- Wet surface.
- Place overlay.
- Cure overlay 3 hours.
- Open lane at 5 a.m.

Although this sequence has been used successfully, weekend lane closures are preferred for the construction of LMC-VE overlays and are required for the construction of SF and LMC-HE overlays (Sprinkel, 2006).

23.3.2 Cost

The cost of an overlay is a function of the cost of materials, surface preparation, labor, equipment, overhead, and traffic control. Cost data based on a review of bid tabulations obtained from the Virginia Department of Transportation bridge office for the period of 1994 and 1995 indicated the following average total costs per square yard for overlays: LMC and SF, \$130; LMC-HE, \$92; and LMC-VE, \$96 (Sprinkel, 1999). The rapid overlays cost less than the conventional overlay. Traffic control costs are high for conventional overlays because of the requirements for concrete barricades, removing and installing permanent and temporary pavement markings, and longer construction time. The rapid overlays are installed in a short time using cones for delineation and without the need to replace pavement markings, so the traffic control costs are less. The LMC-VE costs more than the LMC-HE because of the higher cost of the cement.

23.3.3 HCC Pavement Overlays

Bonded pavement overlays are similar to bonded bridge deck overlays, and the concrete mixtures and construction procedures are similar. One difference is that a slip-form concrete paving machine is used for pavement overlays and a bridge deck vibrating screed is used for bridge deck overlays. The slump of the overlay concrete used on pavements is typically 1 to 4 in., and the slump of the overlay concrete used on decks is typically 4 to 7 in. Overlays on decks can increase the stiffness of the deck, but the increase is typically not a significant factor in the performance of the deck. On the other hand, overlays are often placed on pavements to increase the stiffness of the pavement which should extend the life of the pavement. Deflections were reduced by 33 and 36%, respectively, after 2- and 4-in.-thick overlays were placed on 8-in.-thick continuously reinforced pavements in Virginia (Mokarem et al., 2007; Sprinkel and Ozyildirim, 1999a, 2000a). The increased stiffness has been maintained for 10 years, and it is anticipated that the overlays will perform well for 20 years or more.

23.3.4 Service Life of HCC Overlays

The service life of an overlay is usually controlled by a failure in the vicinity of the bond interface between the overlay and the deck or pavement surface. The service life of a well-bonded overlay is usually reduced by cracks and construction joints. Joints and full-depth cracks increase the probability of delamination of the overlay in the vicinity of joints and cracks. The delaminations often spread to other areas. Joints and cracks may control the time to repair of properly constructed overlays. Other common causes of failure are due to the overlay being placed on deck or pavement concrete that is deteriorating or on deck concrete that is salt contaminated and the reinforcement is corroding.

The service life of a well-bonded deck overlay with no full-depth cracks and joints placed on concrete in good condition should be controlled by the time it takes for the overlay to allow chlorides to reach the reinforcement in the deck and cause corrosion-induced spalling; however, many years are required for chlorides to penetrate the low-permeability overlays, and this type of failure is unlikely (Sprinkel, 2003a, 2004a). Also, loss of skid resistance or loss of ride quality rarely controls the life of a hydraulic cement concrete overlay. The exception is when ride quality is affected by the presence of spalling caused by low bond strength or corrosion or by reinforcement in situations where the reinforcement was corroding when the overlay was placed. It is reasonable to expect that the service life of overlays will increase with an increase in bond strength, with a decrease in the incidence of cracking and construction joints, with a decrease in permeability, and with a decrease in chloride at the level of the deck reinforcement.

The probability that long-lasting HCC overlays will be constructed increases with the use of low-shrinkage concrete mixtures; the use of good surface preparation procedures; proper consolidation of the overlay; placement of overlays when evaporation rates are low; good curing of the overlay; the construction of 1.25- to 2.0-in.-thick overlays; use of no construction joints; and the construction of overlays on bridges that are rigid and subject to low creep or pavements that have adequate stiffness, good drainage, and good base materials.

23.4 Summary

Properly constructed, HCC overlays can last 30 years or more. The six key issues for long-lasting overlays are contractor performance, material properties, bond strength, thickness, surface characteristics, and protection characteristics of the overlay. HCC overlay properties that support long-lasting overlays include adequate bond strength, low shrinkage, low permeability, and few cracks and construction joints. A sound and stable substrate and good surface preparation are required to obtain adequate bond strength. Quality mixture proportions that provide low shrinkage, low permeability, and few cracks are required to protect the deck from chlorides and moisture. Proper placement that includes adequate consolidation, strike off, and finishing is required to obtain good bond strength and low permeability. Good curing that minimizes cracking and premature loading is required for long-lasting protection of the deck. Other factors include construction of overlays with a thickness of 1.25 to 2 in. and using as few construction joints as possible. Finally, the contractor must construct an overlay that satisfies the requirements of a good specification.

24.1 Historical Development

The development of fiber-reinforced concrete material has undergone a number of phases. In the 1960s, research by Romualdi and coworkers (Romualdi and Batson, 1963; Romualdi and Mandel, 1964) demonstrated the effectiveness of short steel fibers in reducing the brittleness of concrete. This development has continued with expansion to a variety of other fibers, such as glass, carbon, synthetics, natural fibers, and, in recent years, hybrids that combine either different fiber types or fiber lengths. The continuously enhanced knowledge of fiber-reinforcement effectiveness has resulted in structural design recommendations by RILEM TC 162-TDF (Vandewalle et al., 2003). This document focuses on fiber-reinforced

* E. Benjamin Wylie Collegiate Chair Professor, Department of Civil and Environmental Engineering, University of Michigan, Ann Arbor; expert on high-performance fiber-reinforced cementitious composites, inventor of engineered cementitious composites.

FIGURE 24.1 Uniaxial tensile stress–deformation relation of concrete, FRC, and HPFRCC. For FRC, deformation after a crack is formed is associated with crack opening δ . Tensile load capacity drops as a single crack enlarges during tension softening. For HPFRCC, deformation during the elastic and strain-hardening stages is properly described as straining. Tensile load capacity continues to rise during multiple microcracking and continued increase in strain. The strain capacity of HPFRCC is defined as the strain value at which peak tensile load is reached.

concrete (FRC) that possesses a tension-softening, quasi-brittle response (Figure 24.1). Apart from the gradual expanded use of the tension-softening branch of FRC in structural property enhancements, fibers in small quantities have been successfully used in controlling restrained drying shrinkage cracks. The subject of FRC is treated in detail in Chapter 22 of this book.

Beginning as early as the 1980s, interest in creating a fiber-reinforced concrete material with tensile ductility has been gaining ground. Within FRC, the toughness of the material is increased but no change in ductility is attained. Ductility is a measure of tensile deformation (strain) capacity typically associated with ductile steel, for example, but not with concrete material. Attempts to achieve tensile ductility in concrete material are exemplified by the early efforts of Aveston et al. (1971) and later Krenchel and Stang (1989), who demonstrated that, with continuous aligned fibers, high tensile ductility hundreds of times that of normal concrete can be attained. The modern-day version of continuous fiber reinforcement is represented by textile-reinforced concrete materials that may be prestressed (Curbach and Jesse, 1999; Reinhardt et al., 2003). Research on pultruded continuous fiber-reinforced concrete was pioneered by Mobasher et al. (2006). In parallel, research into the use of discontinuous fibers at high dosage (4 to 20%), such as in cement laminates (Allen, 1971) and in slurry-infiltrated fiber concrete (SIFCON) (Lankard, 1986; Naaman, 1992), has resulted in concrete composite materials that attain higher tensile strength than normal concrete and are not as brittle, but which have much less ductility than their continuous-fiber and textile-reinforced counterparts.

These materials may be considered a class of materials separate from FRC in that different degrees of tensile ductility are achieved, often accompanied by a strain-hardening response distinct from the tension-softening response of FRC. Naaman and Reinhardt (2003) classified such material as *high-performance fiber-reinforced cementitious composites* (HPFRCC) (Figure 24.1). It should be noted that most members of this class of material have a matrix that does not contain coarse aggregates and should therefore be regarded as fiber-reinforced cement pastes or mortars; however, in keeping with the broadened meaning used in the literature, we shall use the term *concrete material* in this chapter to include concrete, mortar, and cement paste.

Figure 24.1 illustrates the differences between the tensile response of normal concrete, FRC, and HPFRCC, such as obtained from a uniaxial tension test. This figure emphasizes the transition from brittle concrete to quasi-brittle FRC (tension softening) to ductile HPFRCC (strain hardening). Specifically, during tension softening, deformation is localized onto a single fracture plane, most appropriately described in terms of crack opening. During strain hardening, deformation is composed of the opening of multiple subparallel fine cracks and elastic stretching of the material between these cracks. Over a

FIGURE 24.2 Two classes of HPFRCCs: (a) Tensile stress-elongation relationship for high-strength Ductal® based on prism specimen $70 \times 70 \times 160$ mm with 150-mm gauge length. (Adapted from Chanvillard, G. and Rigaud, S., in *Proceedings of High-Performance Fiber-Reinforced Cement Composites (HPFRCC 4)*, Naaman, A.E. and Reinhardt, H.W., Eds., RILEM, Paris, 2003, pp. 21–34.) (b, c) Tensile stress-strain relationship for ductile ECC, based on coupon specimen $76 \times 13 \times 305$ mm with 180-mm gauge length. (Adapted from Fischer, G. et al., in *Seventh International Symposium on Brittle Matrix Composites*, October 13–15, Warsaw, Poland, 2003, pp. 29–36; Li, V.C. and Wang, S., *ACI Mater. J.*, 99(1), 11–21, 2002.)

length scale that includes many such cracks, the deformation may be considered tensile strain smeared over a representative volume of material. As will be seen in the following sections, these distinctions between FRC and HPFRCC have significant ramifications in terms of load capacity and structural durability.

Whereas the HPFRCC materials mentioned above embody the highly desired tensile properties lacking in normal concrete or in FRC, until recently they have mostly been limited to academic research laboratories or specialized applications. This is due to additional demands in industrial projects, particularly in on-site construction, such as economical feasibility and constructability. These two demands are difficult to meet when either continuous fibers or high fiber content are used in the composites.

In recent years, two new classes of HPFRCC have emerged. Ductal® has a high tensile strength of 12 MPa and a ductility of 0.02 to 0.06% (Chanvillard and Rigaud, 2003). Engineered cementitious composite (ECC), originally developed at the University of Michigan, has a typical moderate tensile strength of 4 to 6 MPa and a higher ductility of 3 to 5% (Fischer et al., 2003; Li, 1993). The tensile stress-strain curves of these two types of HPFRCCs are illustrated in Figure 24.2. The development approach for these two classes of materials is quite different. For Ductal®, which can be traced back to the work of Bache (1981),

the approach is to employ a tightly packed dense matrix to increase both tensile and compressive strength of the material. Fiber is added to counteract the resulting high brittleness of the densified matrix. The dense matrix allows a strong bond with the fiber that results in a high post-cracking strength as long as a fiber with high strength is utilized. For ECC, the approach is to create synergistic interactions between the fiber, matrix, and interface to maximize the tensile ductility through development of closely spaced multiple microcracks while minimizing the fiber content (generally 2% or less by volume). This approach is detailed in Section 24.2.3. Ductal® is designed for use in the elastic stage, so the fiber action becomes effective only when the structural ultimate limit state (ULS) is approached. ECC is generally designed for use in the elastic and strain-hardening (inelastic) stages, so fiber action becomes effective even under normal service loads. The development of ECC is still evolving, even though a number of full-scale structural applications have already appeared in Japan, Europe, and the United States. This chapter summarizes some basic knowledge of ECC. In the following, the fundamental characteristics of ECC are described. This is followed by a section on structural behavior of steel-reinforced ECC elements (R/ECC) and a section on the durability behavior of ECC material and R/ECC.

The literature on ECC is rapidly expanding with contributions from academic research and industrial organizations around the world. Some good sources of references include recent workshop or conference proceedings on this subject, such as HPFRCC in Structural Applications (Fischer and Li, 2006), FraMCoS-6 (Carpinteri et al., 2007), and HPFRCC 5 (Reinhardt and Naaman, 2007). These documents contain a number of papers on ECC and related subjects. To assist in the transition to broader industrial use, the Japan Society of Civil Engineers has published a design guideline (JSCE, 2007; Rokugo et al., 2007), and the RILEM TC HFC technical committee will be publishing two state-of-the-art reports on this subject. To aid the reader in maneuvering this literature, some clarification on semantics will be helpful. The name *engineered cementitious composite* (ECC) was adopted by the original developers (Li, 1993) to emphasize the micromechanics basis behind the design of this material. Micromechanics serves as a powerful tool to guide materials design for targeted composite properties and enables meaningful linkage between materials engineering and structure performance design (Li, 2007). In 2006, the RILEM TC HFC technical committee decided to emphasize the unique tensile strain-hardening response of this material (Figure 24.1) as a constitutive law for structural engineering design and gave the more descriptive name *strain-hardening cementitious composite* (SHCC) to this class of materials. The Japan Society of Civil Engineers, however, prefers to emphasize the multiple fine cracking (and associated durability; see Section 24.5), thus they refer to the material as *multiple fine cracking fiber-reinforced cementitious composite*. In essence, all of these materials are designed using micromechanical tools and represent identical material technology.

24.2 General Characteristics

24.2.1 The Family of ECC Materials

Engineered cementitious composite can be regarded as a family of materials with a range of tensile strengths and ductilities that can be adjusted depending on the demands of a particular structure. ECC also represents a family of materials with different functionalities in addition to the common characteristics of high tensile ductility and fine multiple cracking. Self-consolidating ECC (e.g., ECC M45 and its variants) is designed for large-scale, on-site construction applications (Kong et al., 2003; Lepech and Li, 2007). High-early-strength ECC (HES-ECC) is designed for applications that require rapid strength gain, such as transportation infrastructure that must be quickly reopened to the motorist public (Wang and Li, 2006a). Lightweight ECC (LW-ECC) is designed for applications where the dead load of structural members must be minimized (Wang and Li, 2003). Green ECC (G-ECC) is designed to maximize material greenness and infrastructure sustainability (Lepech et al., 2007; Li et al., 2004b). Self-healing ECC (SH-ECC) emphasizes the functionality of recovering transport and mechanical properties after experiencing damage (Li and Yang, 2007; Yang et al., 2005).

TABLE 24.1 Major Physical Properties of ECC

Compressive Strength (MPa)	First Crack Strength (MPa)	Ultimate Tensile Strength (MPa)	Ultimate Tensile Strain (%)	Young's Modulus (GPa)	Flexural Strength (MPa)	Density (g/cc)
20–95	3–7	4–12	1–8	18–34	10–30	0.95–2.3

Engineered cementitious composite using local material ingredients has been successfully produced in various countries, including Japan (Kanda et al., 2006a,b), Europe (Mechtcherine and Schulze, 2006), and South Africa (Boshoff and van Zijl, 2007), in addition to the United States. To successfully develop local versions of ECC, a good understanding of the underlying design approach is helpful (Kanda and Li, 1999; Li, 1993). A synopsis of the ECC design approach is given in Section 24.2.3.

A summary of major physical properties of ECC is given in Table 24.1. It should be emphasized that ECC properties can be tailored by the use of micromechanics tools. Even broader ranges of properties beyond those in this table can be expected in the future as the need arises. The very high strength and modulus version was attained by Kamal et al. (2007). The very high tensile ductility version was reported in Li et al. (1996). The super lightweight version was described in Wang and Li (2003). The common characteristic of these ECC materials is that they have tensile ductility orders of magnitude higher than those in typical concrete or FRC materials.

It should be noted that, although a large body of literature has developed around ECC based on polyvinyl alcohol fiber, commonly referred to as PVA-ECC, other fibers have been successfully utilized. These include high-modulus polyethylene (PE) fibers (Kamal et al., 2007; Li, 1993; Li and Wang, 2002) and polypropylene (PP) fibers (Takashima et al., 2003; Yang and Li, 2008). The principle behind the design of ECC, as discussed in Section 24.2.3, does not depend on a particular fiber. Fibers with certain properties, however, may meet the criteria for tensile strain hardening at a lower volume fraction. Decisions on what fibers to use will depend on their natural characteristics, including mechanical characteristics, diameter ranges, and surface characteristics; on the resulting ECC mechanical, durability, and sustainability performance; and on economics.

24.2.2 Tensile Characteristics

As indicated earlier, the most important characteristic of ECC is the high tensile ductility represented by a uniaxial tensile stress–strain curve with strain capacity as high as 5% (Figure 24.2b,c and Figure 24.3). This metal-like behavior shows a characteristic *yield point* at the end of the elastic stage when the first

FIGURE 24.3 A tensile stress–strain curve of an ECC, showing also the crack width development (square symbols) as a function of imposed tensile strain.

microcrack appears on the specimen. Subsequent increase in load results in a strain-hardening response—that is, a rise in tensile deformation (volumetric straining in the form of multiple microcracking as opposed to localized crack opening) accompanied by a rise in load. Final failure of the specimen occurs when one of the multiple cracks forms a fracture plane. Beyond this peak load, ECC is no different than normal FRC, showing a tension-softening response. The high tensile ductility is of great value in enhancing the structural ultimate limit state (ULS) in terms of structural load and deformation capacity as well as energy absorption. In this manner, ECC can offer structural safety improvements. This contribution of ECC to structural response enhancement is discussed further in Section 24.4.

The formation of multiple microcracking is necessary to achieve high composite tensile ductility. Between first cracking strain (about 0.01%) and 1% strain, the microcrack opening increases from 0 to about 60 μm . Further loading beyond 1% causes more multiple cracks to form, but with no additional crack opening beyond the steady-state value of 60 μm (Figure 24.3). Governed by the mechanics of the fiber–matrix interaction within ECC, this unique characteristic is critically important for durability (see Section 24.5) of both material and structure. Unlike concrete or FRC, the steady-state crack width is an intrinsic material property, independent of loading (tension, bending, or shear), structure size and geometry, and steel reinforcement type and amount. This observation has important implications in service life, maximum member size, economics, and architectural aesthetics. In short, where steel reinforcement is used to control crack width in concrete, such steel reinforcement can be completely eliminated in ECC. By suppressing cracks with large crack width even in the presence of large imposed structural deformations, ECC can offer structural durability improvements in addition to watertightness and other serviceability enhancements. Although Figure 24.3 shows a particular example of ECC with steady-state crack width at 60 μm , even tighter crack widths, as low as 20 μm , have been achieved (Yang et al., 2007).

24.2.3 ECC Material Design Considerations

To attain high tensile ductility and tight microcrack width while keeping the fiber content low (2% or less by volume), ECC has been optimized through the use of micromechanics (Li, 1993; Li and Leung, 1992). Micromechanics is a branch of mechanics applied at the material constituent level that captures the mechanical interactions among the fiber, mortar matrix, and fiber–matrix interface. Typically, fibers are of the order of millimeters in length and tens of microns in diameter, and they may have a surface coating on the nanometer scale. Matrix heterogeneities in ECC, including defects, sand particles, cement grains, and mineral admixture particles, have size ranges from nano- to millimeter scale. Ideally, the micromechanics model should capture all of the deformation mechanisms at the millimeter, micrometer, and nanometer scales; however, simplifying assumptions have been made to make the model equations tractable, and the resulting conditions (in closed-form solution) for strain hardening can be used as guidelines for material component tailoring. These conditions are expressed in strength and energy terms, as shown in Equation 24.1:

Strength criterion

$$\sigma_0 \geq \sigma_{cs} \quad (24.1a)$$

Energy criterion

$$J'_b \equiv \sigma_0 \delta_0 - \int_0^{\delta_0} \sigma(\delta) d\delta \geq J_{tip} \approx \frac{K_m^2}{E_m} \quad (24.1b)$$

where σ_{cs} and σ_0 are the cracking strength and maximum fiber bridging capacity on each potential crack plane; δ_0 is the crack opening corresponding to σ_0 in the fiber bridging relationship $\sigma(\delta)$, which goes through a maximum; J_{tip} and J'_b are the crack tip matrix toughness and the complementary energy of the fiber bridging relation, respectively; and K_m and E_m are the matrix fracture toughness and Young's modulus, respectively. For derivation of Equation 24.1, see Li (1993). Physically, the strength criterion (Equation

FIGURE 24.4 Illustration of the energy criterion for multiple cracking: (a) When Equation 24.1b is not satisfied, the common Griffith-type crack propagation results. Crack opening at the middle δ_m will exceed δ_0 , causing spring failure and subsequent tension softening. (b) When Equation 24.1b is satisfied, the steady-state flat crack propagation mode prevails, with δ_{ss} staying below δ_0 .

24.1a) ensures the initiation of microcracks from initial flaw sites in the composite before the tensile load exceeds the maximum fiber bridging capacity. The left-hand side of Equation 24.1a can be thought of as the maximum tensile load carried by a line of springs with tensile strength determined by the bridging fibers. Failure of the fiber springs is associated with fiber rupture, slippage, or pullout. Ensuring that the maximum fiber bridging capacities on existing crack planes remain higher than the matrix cracking strength of potential new crack planes allows additional cracks to form; otherwise, saturated multiple cracking would not be attained, and sparsely spaced cracks will result, limiting the tensile ductility.

The energy criterion (Equation 24.1b) prescribes the mode of crack propagation once initiated. The normal form of Griffith cracking is not favorable to multiple cracking. This is because the crack opening in Griffith-type cracks, especially at the midpoint of the crack line (δ_m), always increases with the length of the crack, and failure of the bridging fiber invariably results, either in the form of fiber pullout or breakage beginning at this widest point when δ_m exceeds δ_0 . The only means of preventing this is by altering the Griffith crack propagation mode to a flat crack propagation mode whereby the crack extends while the crack opening remains constant at any location (apart from a small bridging zone near the crack tip) regardless of the length of the crack. In this manner, δ_m stays below δ_0 along the entire crack line. During flat crack propagation, energy is exchanged between work input (from applied loading) and energy absorbed by the fiber bridging process in the opening of the crack near the crack tip (and only near the crack tip), as well as matrix material breakdown at the crack tip. The enforcement of energy balance results in Equation 24.1b. Violation of Equation 24.1b results in fracture localization, as in the case of FRC, and terminates the multiple cracking process. The energy criterion is illustrated in Figure 24.4.

It should be noted that both parts of Equation 24.1 have been arranged so the left-hand sides of the inequality sign contain terms that pertain to fiber and interface properties, while the right-hand sides contain terms that pertain to matrix properties, all of which are measurable physical properties. This observation emphasizes the usefulness of Equation 24.1 to aid in the fiber, matrix, and interface selection or tailoring process to arrive at viable compositions of ECCs. As an example, this approach has been adopted for tailoring of the surface coating on PVA fibers (Li et al., 2002) and for the deliberate introduction of matrix defects in lightweight ECC (Wang and Li, 2003) and high-early-strength ECC (Wang and Li, 2006a). The equality signs in Equation 24.1 are based on the assumption that initial defect size and fiber volume fraction are uniform throughout the composite. In reality, variability of these

FIGURE 24.5 (a) Compressive strength development of ECC (M45), and (b) ECC specimen after compressive strength test. (From Wang, S. and Li, V.C., in *Proceedings, High-Performance Fiber-Reinforced Cementitious Composites (HPFRCC) in Structural Applications*, Fischer, G. and Li, V.C., Eds., RILEM, Paris, 2006, pp. 65–73.)

parameters must exist and depends on the mix composition as well as mixing procedure. This variability creates the need for a wider margin between the left- and right-hand sides of Equation 24.1 and explains the use of the inequality signs. Kanda and Li (2006) specifically studied the necessary margin to create robust tensile properties.

24.2.4 Compressive and Flexural Characteristics

The compressive properties of ECC are not significantly different from normal- to high-strength concrete. Compressive strengths of ECC range from 20 to 95 MPa. The elastic modulus of 15 to 34 GPa is typically lower than that for concrete due to the absence of coarse aggregates. The compressive strain capacity of ECC is slightly higher, around 0.45 to 0.65%. Figure 24.5a shows a strength development curve for an ECC (M45) compressive cylinder. The post-peak behavior of ECC under compression tends to descend more gently than high-strength concrete, accompanied by a gradual bulging of the specimen (Figure 24.5b) rather than explosive crushing failure. The flexural response of ECC reflects its tensile ductility (Kunieda and Rokugo, 2006a; Maalej and Li, 1994; Wang, 2005; Wang and Li, 2006). Under bending, multiple microcracking forms at the base of the beam, allowing it to undergo a large curvature development, a phenomenon that has resulted in the popular name of *bendable concrete*. A flexural strength (modulus of rupture, or MOR) of 10 to 15 MPa is easily achievable and is accompanied by a significant deflection-hardening regime (Figure 24.6a). Deflection hardening is an intrinsic property of ECC that does not depend on geometry. This is not the case for tension-softening FRC, for which deflection hardening becomes more difficult to attain as beam height increases (Stang and Li, 2004). A highly deformed ECC beam and fine multiple cracking on the tensile side of the beam are shown in Figure 24.6b,c (Wang, 2005; Wang and Li, 2006b). Engineered cementitious composite has significant improvements in fatigue response over normal concrete and FRC. Suthiwarapirak et al. (2002) conducted flexural fatigue tests on ECC and demonstrated higher ductility and fatigue life compared with polymer cement mortars commonly used in repair applications.

24.3 Mixture Proportioning, Material Processing, and Quality Control

Table 24.2 gives a typical mix design for ECC (ECC-M45) with self-consolidating casting properties. All proportions are given with materials in the dry state. The ingredients and mix proportions have been optimized to satisfy the multiple cracking criteria (Equation 24.1). Specifically, the type, size, and amount of fiber and matrix ingredients, along with interface characteristics, are tailored for multiple cracking

FIGURE 24.6 (a) Flexural load–deflection curve of an ECC, (b) ECC flexural specimen showing large deflection, and (c) fine multiple cracking on the tensile side of beam 304 mm (length) \times 76.2 mm (width) \times 25.4 mm (depth). (Adapted from Wang, S. and Li, V.C., in *Proceedings, High-Performance Fiber-Reinforced Cementitious Composites (HPRCC) in Structural Applications*, Fischer, G. and Li, V.C., Eds., RILEM, Paris, 2006, pp. 65–73.)

and controlled crack width. ECC incorporates fine silica sand with a sand/binder ratio (S/B) of 0.36 to maintain adequate stiffness and volume stability. ECC-M45 has a water/binder (w/b) ratio of 0.26 to attain a good balance of fresh and hardened properties. The binder system is defined as the total amount of cementitious material (i.e., cement and fly ash, Type F) in ECC. The silica sand has a maximum grain size of 250 μm and a mean size of 110 μm . The aggregated particle size of all matrix components should be properly graded to achieve self-consolidating fresh properties (Fischer et al., 2003).

Various fiber types have been used in the production of ECC, but ECC-M45, which currently has the largest experimental dataset, uses polyvinyl alcohol (PVA) fiber 12 mm in length and 39 μm in diameter. The nominal tensile strength, stiffness, and density of the fiber are 1600 MPa, 40 GPa, and 1300 kg/m^3 , respectively. The PVA fiber is surface coated by a proprietary oiling agent (1.2% by weight) to reduce the fiber–matrix interfacial bonding. To account for material heterogeneity, a fiber content of 2% by volume, which is greater than the calculated critical fiber content required to achieve strain hardening, is typically used in the mix design. The mix design described above has been experimentally demonstrated in a broad range of investigations to consistently produce good ECC fresh and hardened properties. A high-range

water-reducing (HRWR) admixture containing a polycarboxylate chemical composition has been found to be most effective in maintaining the desired fresh property during mixing and placing. Adaptations of this reference mix have been used in various construction projects. Full-scale production of ECC was carried out in Japan (Kunieda and Rokugo, 2006b) and in the United States (Lepech and Li, 2007). Experience in concrete ready-mix plants suggests the charging sequence of raw material shown in Table 24.3.

The properly mixed ECC material should have a creamy texture, as shown in Figure 24.7. To ensure good self-consolidation behavior, the deformability of ECC in the fresh state should be checked at the construction site. To perform this check, a standard concrete slump cone is filled with fresh ECC material and emptied onto a level Plexiglas® or glass plate. The flowable ECC material flattens into a large pancake-shaped mass (Figure 24.8a). Two orthogonal diameters of this “pancake” are measured, and a characteristic deformability factor, denoted by Γ , is calculated:

$$\Gamma = \frac{(D_1 - D_0)}{D_0} \quad (24.2)$$

where D_1 is the average of two orthogonal diameter measurements after slump cone removal, and D_0 is the diameter of the bottom of the slump cone. For good self-consolidation, Γ should have a minimum value of 2.75 (Lepech and Li, 2007). Excessively large values of Γ , however, may indicate improper mix proportions, may potentially result in component segregation, and must be avoided. Typically, the

FIGURE 24.7 Creamy texture appearance of fresh ECC in mixing drum of a ready-mix truck. (From Lepech, M.D. and Li, V.C., *ACI Mater. J.*, 2008.)

FIGURE 24.8 (a) Slump cone test of ECC flowability; (b) Marsh cone flow rate test.

deformability value decreases over time during mixing and transport in the ready-mix concrete truck. The use of a hydration stabilizer has been found effective in maintaining good deformability without negatively affecting the hardened properties. To minimize the danger of early-age cracking, wet curing for a minimum of 7 days and nighttime casting of field applications are recommended for ECC when the air temperature is above 50°F.

Care must be taken to ensure good fiber dispersion in the mix. Yang et al. (2007) found that an effective means of controlling fiber dispersion is to ensure good mortar viscosity via a Marsh flow cone test. In the Marsh cone flow test, the funnel is filled completely with mortar (ECC mortar without fibers), and the bottom outlet is then opened, allowing the mortar to flow (Figure 24.8b). The Marsh cone flow time of mortar is the elapsed time in seconds between the opening of the bottom outlet and the time when light becomes visible at the bottom, when observed from the top.

In addition to the standard compression cylinder test typically applied to concrete quality control on job sites, the tensile coupon test should also be carried out to ensure that the tensile properties specified in design documents are met. These compression and tensile tests should be conducted at the ages of 4

days, 7 days, 14 days, and 28 days to observe property development over time. It is recognized that uniaxial tension tests are difficult to carry out on a routine quality control basis. As a result, a simpler bending test accompanied by inversion schemes to obtain material tensile properties is being developed (Kanakubo, 2006; Qian and Li, 2007).

Apart from ready-mix and self-consolidating casting, special versions of ECC have also been developed for extrusion (Stang and Li, 1999) and shotcreting (Kanda et al., 2001; Kim et al., 2003; Kojima et al., 2004). Precasting of ECC structural elements has been utilized for coupling beams in high-rise buildings in Japan (Kanda et al., 2006a,b). Kanda et al. concluded that full-scale production in a precast plant of ECC with high mechanical performance and excellent fluidity is achievable in practice. Figure 24.9 shows the various methods of ECC material processing. Although these ECC materials all carry the same hardened material characteristics described in Section 24.2, they exhibit significantly different fresh properties to meet different processing requirements. The relatively small amount of fibers used in ECC allows such versatility in processing methods.

24.4 Behavior of ECC Structural Elements

A variety of experiment programs have been performed to assess the performance of ECC at the structural element level for both seismic and non-seismic structural applications (Table 24.4). These experiments provide insight into how unique ECC material properties elevate the response performance of the structure. Within this section, we describe some observed responses of elements subjected to monotonic and fatigue flexural loading, cyclic shear loading, and steel–ECC interactions. Fundamental knowledge will then be drawn from these studies.

24.4.1 Structural Response of R/ECC Elements

24.4.1.1 Flexural Elements

Fischer and Li (2002a) studied the behavior of R/ECC flexural elements under reversed cyclic loading. The test setup is shown in Figure 24.10, and the specimen configuration is shown in Figure 24.11. A regular reinforced-concrete (R/C) beam was also tested as control. Figure 24.12 shows the substantial difference in hysteretic response for the R/ECC and the R/C control column specimens. A significantly fuller hysteretic loop with larger energy dissipation was achieved by the R/ECC beam despite the fact that no shear stirrups were used at the base of the flexural element. The damage experienced by these elements at 10% interstory drift is compared in Figure 24.13. Even at this high drift level, no spalling of the ECC was observed. In contrast, the R/C column lost all concrete cover near the fixed end subsequent to bond splitting and spalling. Clearly, the R/ECC element demonstrated significant damage tolerance under severe loading.

The high cycle fatigue response of R/ECC flexural elements was studied by Kim et al. (2004) in conjunction with a bridge deck link slab application. The full-thickness slab test configuration is provided in Figure 24.14, which shows the steel girder (anchored to the slab by steel studs) on top for convenience of testing. Over 100,000 cycles, no degradation in stiffness was observed in the R/ECC or in the R/C control beam; however, the cracks in the R/C beam grew continuously to 0.6 mm at the end of the test, while the microcracks in R/ECC beam remained at approximately 50 μm (Figure 24.15).

Motivated by the need to increase the stiffness and to reduce the tendency for fatigue cracking in steel bridge decks, a steel/ECC composite beam was studied by Walter et al. (2004) under monotonic flexural loading (Figure 24.16). For control, a steel/FRC and a steel/FRD composite beam were also tested in the same configuration. FRD is a fiber-reinforced Densit® material, a very high strength and dense concrete reinforced with steel fibers similar to Ductal®. All concrete materials were cast onto the steel plate and bonded only by adhesion to the roughened steel surface. The load-deflection response captured in Figure 24.17 demonstrates a much higher load capacity in the case of the steel/ECC beam, which showed multiple microcracking during testing, suppressing the formation of a brittle fracture that limits the capacity of the steel/concrete beam. The single fracture in the FRC and FRD beams led to their immediate debonding from the steel plate.

24.4.1.2 Shear Element

Fukuyama et al. (2000) studied the behavior of R/ECC shear elements under reversed cyclic loading. The specimen configuration is shown in Figure 24.18, and the hysteretic loops for R/ECC and R/C are shown in Figure 24.19. Again, the hysteretic loops for R/ECC showed much greater stability and ability to dissipate energy. The R/C specimen suffered extensive bond splitting and loss of cover, accompanied by large diagonal cracks. In contrast, the damage experienced by the R/ECC shear element was significantly lower (Figure 24.20). No bond splitting or cover loss was observed, and microcracks continued to carry

FIGURE 24.11 Specimen configurations of flexural elements: (a) R/C; (b) R/ECC with no stirrups in shear zone. (From Fischer, G. and Li, V.C., *ACI Struct. J.*, 99(6), 781–790, 2002.)

loads up to a 5% rad deflection angle. The shear capacity of a R/ECC beam can be estimated from a linear superposition of the contributions of the ECC material and the shear and axial steel reinforcements due to the compatible deformation of the two materials even after steel yields. This approach was suggested to be reasonably accurate and conservative (Rokugo et al., 2007); however, numerical analysis combined with experimental data (Kabele and Kanakubo, 2007) suggested that only a fraction of the tensile strength and strain capacity of ECC might be utilized in the shear element due to possible damage of bridging fibers on sliding crack surfaces.

24.4.1.3 Column Element

The response of R/ECC and R/C columns under fully reversed cyclic loading was studied by Fukuyama et al. (2000). These columns were tested under the antisymmetrical moment condition. The axial force applied to the column was 20% of the axial compressive strength of the column, calculated without the contribution of the steel reinforcements. The hysteretic behavior in terms of stability and energy dissipation was improved in the R/ECC column over the R/C column in a manner similar to that for flexural and shear elements (Figure 24.21). Large bond splitting cracks were observed in the R/C column, which

FIGURE 24.21 Hysteretic behavior of columns under fully reversed cyclic loading for (a) R/C and (b) R/ECC. (From Fukuyama, H. et al., in *Proceedings of the 6th ASCCS International Conference on Steel–Concrete Composite Structures*, March 22–24, Los Angeles, CA, pp. 969–976.)

FIGURE 24.22 Test setup for beam–column connection. (From Parra-Montesinos, G. and Wight, J.K., *ASCE J. Struct. Eng.*, 126(10), 1113–1121, 2000.)

failed by shear without yielding of the longitudinal reinforcements; subsequently, the resistant shear force in the envelope curve of shear force–deflection angle relationship decreased with increase of deflection angle. On the other hand, the R/ECC column did not fail by shear or bond splitting. Instead, it maintained a ductile response up to the end of the test with fine cracks revealed on the specimen surface.

24.4.1.4 Beam–Column Connection Element

Beam–column connection was studied by Parra-Montesinos and Wight (2000), using the test setup shown in Figure 24.22. The hysteretic response for the R/ECC shear panel was substantially improved over the R/C (Figure 24.23), even when all shear stirrups were removed in the R/ECC shear panel. Under fully reversed cyclic loading, a set of orthogonal cracks formed in both specimens (Figure 24.24). Although the orthogonal cracks in R/ECC were much more closely spaced, they did not lead to surface spalling as is often observed in R/C specimens after large load reversals. In addition, edge spalling was revealed in the R/C specimen, associated with the bearing of the steel beam on the brittle concrete. This was not found in the R/ECC specimen.

24.4.1.5 Wall Panel Element

Wall panel elements were studied by Kesner and Billington (2005) under fully reversed cyclic loading, using the test setup shown in Figure 24.25. These tests confirmed that the R/ECC wall panels outperformed the R/C wall panels in hysteretic loop stability, peak load, and energy dissipation (Figure 24.26).

24.4.2 Insights from R/ECC Element Response

The structural element experimental testing results briefly summarized in Section 24.4.1 share the common features of enhanced element load and deformation capacity, hysteretic loop stability, and energy dissipation. Further, structural damage is limited to microcracking while large fractures in the form of bond splitting and spalling are suppressed. A number of helpful insights for structural use of ECC can be drawn from the above studies. These are summarized below.

24.4.2.1 Potential for Reduction or Elimination of Shear Reinforcement

Through the formation of multiple cracks and delay of fracture localization, the ductility of R/ECC elements can be maintained with little or no conventional shear reinforcement. This is best demonstrated in the flexural element (Fischer and Li, 2002a) (Figure 24.11) and beam–column connection (Parra-Montesinos and Wight, 2000) studies highlighted in the previous section, where shear stirrups were completely eliminated. Additional evidence can be found in a study by Li and Wang (2002), who experimentally demonstrated that ECC beams without shear reinforcement exhibited superior performance compared to high-strength concrete beams with closely spaced steel stirrups. Experiments on the cyclic response of unbonded post-tensioned precast columns with ECC hinge zones (Billington and Yoon, 2004) also confirmed that column integrity could be better maintained when concrete is replaced by ECC without any seismic shear detailing.

24.4.2.2 Damage Tolerance

Damage tolerance is a measure of the residual strength of a material or structure when damage is introduced. The damage tolerance of ECC derives from the fact that fracture or real cracks are suppressed in favor of plastic yielding of ECC in the form of multiple microcracks. Such microcracks are not real cracks (Li, 2000) in the sense that an increasing amount of load can be carried across them during ECC strain hardening. Cracks in normal concrete or even in standard fiber-reinforced concrete are accompanied by tension softening, and load-carrying capacity drops as the crack enlarges. As a result, a reliance on steel reinforcement to maintain structural integrity becomes critical. Where no steel reinforcement exists (e.g., in the concrete cover), surface spalling results. Such failure modes are fully eliminated in R/ECC elements, as can be observed in Figure 24.13, Figure 24.20, and Figure 24.24. In these elements, the shear stiffness and the peak load at each load cycle are better maintained than in R/C due to the high damage tolerance of ECC. In structural elements loaded beyond first crack, it is reasonable to expect equal or even higher structural stiffness in R/ECC elements compared to R/C elements, despite the lower elastic modulus of ECC as compared to concrete. This is due to the capability of ECC to continue to share the load-carrying function with steel reinforcements, long after the first crack appears. This concept was verified in an analytic study of cracked reinforced beams by Szerszen et al. (2006). Fukuyama et al. (2007) regarded such damage tolerance functionality of ECC as a significant benefit to society, given the enormous economic cost of repair and reconstruction of infrastructures after a major seismic event that strikes an urban area.

24.4.2.3 Compatible Deformation between ECC and Reinforcement

In R/ECC members with steel reinforcement, both the steel and the ECC can be considered elastic–plastic materials capable of sustaining deformation up to several percent strain. As a result, the two materials remain compatible in deformation even as both steel and ECC yield. Compatible deformation implies that no shear lag exists between the steel and the ECC, resulting in a very low level of shear stress at the steel rebar to ECC material interface. This phenomenon is unique to R/ECC members. As a result of this low interfacial stress between steel and the ECC, the bond between the ECC and reinforcement is not as critical as in normal R/C elements, as stress can be transmitted directly through the ECC material (via bridging fibers) even after microcracking. In contrast, within R/C members stress must be transferred via the rebar–concrete interface to the concrete away from the crack site. After concrete cracks in an R/C element, the concrete unloads elastically near the crack site, while the steel takes over the additional load shed by the concrete. This leads to incompatible deformation and high interface shear stress responsible for the commonly observed failure modes such as bond splitting or spalling of concrete cover. Figure 24.27a shows the stress flow in the composite, before and after matrix cracking, in R/C and R/ECC. The compatible deformation between ECC and reinforcement has been experimentally confirmed (Fischer and Li, 2002b). Figure 24.27b shows the contrasting behavior of R/ECC and R/C near the interface, revealed in a cross-sectional cut of tension-stiffening specimens. In structural elements subjected to large loads such as earthquakes, steel yielding may be expected. In R/C elements, steel yielding may be concentrated at locations where the rebar crosses the concrete cracks due to the large incompatible deformations between the steel and fractured concrete. In R/ECC elements, steel yielding can spread to a much larger volume. As a result, the distributed microcracking in ECC allows for more efficient utilization of steel reinforcement for element energy dissipation. This explains the formation of fuller hysteretic loops observed in the ECC elements discussed in Section 24.4.1 (see Figure 24.12, Figure 24.19, Figure 24.21, Figure 24.23, and Figure 24.26).

24.4.2.4 Tight Crack Width Control and Elimination of Crack Control Reinforcement

A common observation in the structural element tests described is that the cracks generated in the R/ECC have very small crack widths (see Figure 24.13, Figure 24.15, Figure 24.20, and Figure 24.24). This is because crack widths in ECC are self-controlled (Section 24.2.2). Although the presence of steel reinforcement further limits the crack width, ECC material can be easily designed to have crack widths less than 100 μm without depending on steel reinforcement. This small crack width is important with

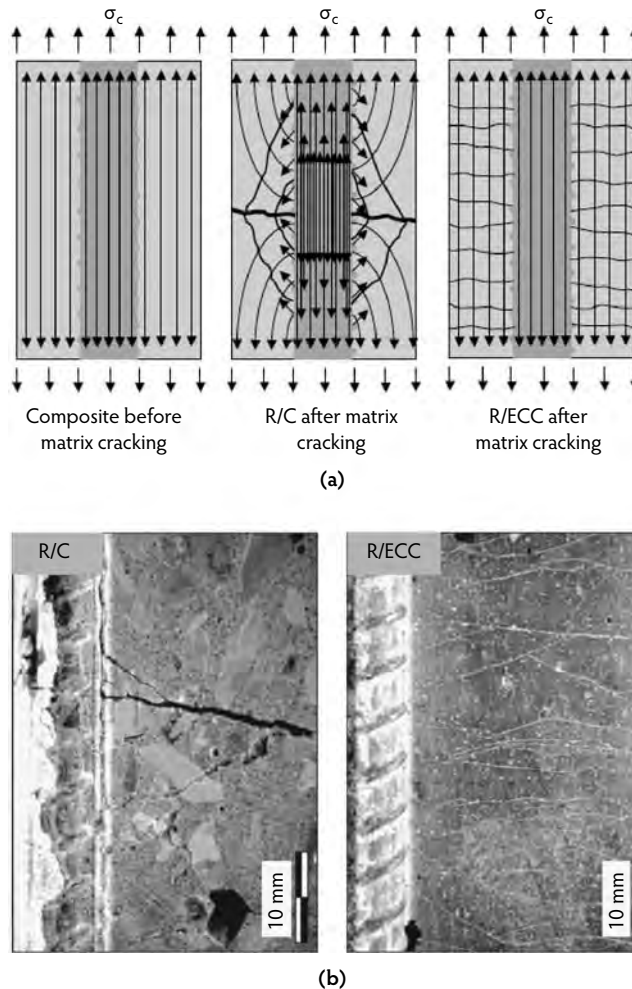

FIGURE 24.27 (a) Stress flow before and after matrix cracking. (b) On the left, brittle fracture of concrete in normal R/C causes unloading of concrete near crack, and a jump in tensile strength, straining the steel locally and resulting in high interfacial shear and bond breakage. On the right, in contrast, compatible deformation occurs between ECC and steel reinforcement with no shear lag, thus maintaining integrity of the interfacial bond. (From Fischer, G. and Li, V.C., *ACI Struct. J.*, 99(1), 104–111, 2002.)

respect to the durability of the structure (Section 24.5) and can be decisive in determining whether a structure requires repair after a major loading event (Fukuyama et al., 2007).

24.4.2.5 Transforming Material Ductility into Structural Strength

Once again, the unique feature of ECC is its ultra-high ductility. This implies that structural failure by fracture is significantly less likely in comparison to normal concrete or FRC. In traditional R/C structural design, the most common and most important material parameter of concrete is compressive strength. For this reason, structural strength (and, more generally, structural performance) is often perceived to be governed by material strength. Essentially, higher material strength (usually referred to as *compressive strength* in the concrete literature) is expected to lead to higher structural strength. This concept is valid only if the material strength property truly governs the failure mode; however, if tensile fracture failure occurs, a high-strength material does not necessarily mean higher structural strength. Instead, a high toughness material, and in the extreme, a ductile material such as ECC can lead to higher structural strength.

A number of experimental observations (Fukuyama et al., 2000; Kanda et al. 1998; Kesner and Billington, 2005; Lim and Li, 1997) provide support for the above reasoning. For example, the shear beam elements tested by Fukuyama et al. (2000) (Figure 24.18) have compressive strengths of 58.3 MPa and 52.5 MPa for concrete and ECC, respectively; however, the structural load capacity was 120 kN vs. 140 kN for the R/C and R/ECC elements, respectively (Figure 24.19). As another example, the precast in-fill wall panels (Figure 24.25) tested by Kesner and Billington (2005) for seismic retrofitting of buildings revealed that a panel with a concrete of compressive strength of 50 MPa attained a structural (shear) strength of 38 kN, while a similar panel made with ECC material of lower compressive strength (41 MPa) achieved a much higher structural strength of 56 kN (Figure 24.26). The over 35% structural strength gain in the R/ECC panel can be attributed to the material ductility of the ECC which prolonged integrity of the panel to a larger drift level. Similarly, detailed numerical analysis (Kabele, 2001) of a wall panel made with ECC demonstrated a structural strength three times that of the panel made with FRC, despite the fact that both materials had the same tensile and compressive strengths.

24.5 Durability of ECC and ECC Structural Elements

24.5.1 Material and Element Durability

As a new construction material, it is not enough to have excellent mechanical performance compared with conventional concrete or FRC. It is also important to verify the durability of the ECC material itself in various environments typical of where such materials are expected to be used. In addition, the influence of this material on structural durability performance of R/ECC must also be confirmed. In most cases, laboratory studies are performed under accelerated conditions; however, long-term performance in the field is most valuable even though it is difficult to obtain, especially for a relatively new material.

Because the greatest value of ECC lies in its superior tensile ductility, this material will likely be used in structures that impose large deformations on the material. This implies that the structure must remain serviceable even if the material undergoes tensile strain hardening accompanied by multiple microcracking. For this reason, the examination of ECC material durability should be carried out in the deformed cracked state; that is, the ECC specimen should undergo preloading to varying strain levels to deliberately create microcrack damage, prior to accelerated exposure tests. Experimental data thus determined from preloaded specimens may be considered as material durability properties under combined mechanical and environmental load. It should be noted, however, that most of these experiments were undertaken with cracked specimens in the unloaded state for experimental testing convenience. On unloading, crack widths in ECC tend to reduce by 10 to 20% from the loaded state. This reduced crack width is used in all experimental data reported. This difference from field conditions where cracks are typically under load is not expected to have a significant impact on the measured durability of ECC material or R/ECC structures but should be verified in future studies.

As will become clear in the following subsections, the durability of ECC and especially of ECC structures can be sensitive to the width of the microcracks. Microcrack widths are therefore designed to be small, typically less than 100 μm for ECC, and potentially much lower. These cracks remain small under fatigue loading, as indicated in Section 24.4.1.1; however, a recent study by Boshoff and van Zijl (2007) indicates that crack width may open wider under sustained loading due to creep mechanisms. Care must be taken for the long-term durability of a structure under combined conditions of sustained loading, deformation to the strain-hardening stage, and exposure to an aggressive environment.

In Section 24.5.2, current knowledge of ECC durability under various environments is summarized. In Section 24.5.3, the durability of R/ECC under chloride exposure is presented. This discussion is followed in Section 24.5.4 by highlights of limited long-term performance data on ECC materials already in structures exposed to the natural environment and (in one case) in combination with mechanical loads. Additional studies of ECC under various environmental or loading conditions can be found in the references in Table 24.5. Most of the durability studies covered here are for ECC reinforced with PVA fibers. The durability of PVA fiber itself has been summarized by Horikoshi et al. (2006).

24.5.2 ECC Durability under Various Environments

In this section, current knowledge on long-term strain capacity, as well as ECC exposed to various commonly encountered environments is summarized. These environments include freeze–thaw cycles, hot–wet cycles, chloride immersion, deicing salt exposure, and alkali–silica reaction (ASR) resistance.

24.5.2.1 Long-Term Tensile Strain Capacity

For a construction material to be considered truly durable, its mechanical properties must not degrade over time and fall below minimum design specifications. To validate ECC long-term effectiveness, a series of tensile tests were performed to determine long-term strain capacity. Due to the continued hydration process typical of cementitious materials and the delicate balance of the cement matrix, fiber, and matrix–fiber interface properties in ECC, the strain capacity of ECC evolves with age during maturing (Li and Lepech, 2004). This is exhibited in a plot of ECC strain capacity vs. age (Figure 24.28). Roughly 10 days after casting, peak strain capacity is achieved when an optimal balance of the matrix, fiber, and matrix–fiber interface properties is attained for highly saturated multiple cracking. As hydration continues, the increasing matrix toughness leads to a reduced composite ductility. Maturity of matrix and matrix–fiber properties eventually results in an ECC long-term steady strain capacity of 3%, far above

FIGURE 24.28 Tensile strain capacity of ECC as a function of age after casting. (From Li, V.C. and Lepech, M., in *Proceedings of the Transportation Research Board 83rd Annual Meeting*, Compendium of Papers CD ROM, Paper 04-4680, Transportation Research Board, Washington, D.C., 2004.)

FIGURE 24.29 Relative dynamic modulus of normal concrete and three versions of ECC, all without air entrainment. (From Li, V.C. et al., *Durable Link Slabs for Jointless Bridge Decks Based on Strain-Hardening Cementitious Composites*, RC-1438, Michigan Department of Transportation, Lansing, 2003.)

the deformation demand imposed by many structural applications but significantly less than the 5% capacity seen at early age. Although long-term tests have only been carried out to 180 days, the long-term strain capacity is expected to remain at approximately 3%. The strain capacity–age curve can be seen as analogous to the compressive strength development curve in normal concrete; however, because it is not monotonically rising, the long-term value should be used for design purposes. For simplicity, 90% of the 28-day strain capacity value that approaches asymptotically to the long-term behavior may be adopted as the design strain capacity. This simplifies the design process, as the same 28-day value is used for compressive strength specification.

24.5.2.2 Freeze–Thaw Durability

Durability of non-air-entrained ECC specimens was tested by exposure to cycles of freezing and thawing, in accordance with ASTM C 666 (ASTM, 2003a). Non-air-entrained concrete specimens were also tested as reference specimens. Testing of ECC and concrete prism specimens was conducted concurrently over 14 weeks (Li et al., 2003). After 5 weeks (110 cycles), the concrete specimens had severely deteriorated, requiring removal from the freeze–thaw machine, as mandated by the testing standard; however, all ECC specimens survived the test duration of 300 cycles with no degradation of dynamic modulus (Figure 24.29). This performance resulted in a durability factor of 10 for concrete compared to 100 for ECC, as computed according to ASTM C 666. In uniaxial tension tests performed on wet-cured- and freeze–thaw-exposed ECC tensile coupons at the same age, no significant drop in strain capacity was experienced after 300 cycles. Both wet-cured and freeze–thaw specimens exhibited a strain capacity of roughly 3%.

24.5.2.3 Tropical Climate Exposure

In contrast to the freeze–thaw tests discussed above, which are designed to simulate temperature changes in winter conditions, hot-water immersion tests were conducted to simulate the long-term effects of hot and humid environments. To examine the effects of environmental exposure, hot-water immersion was performed on individual fibers, single fibers embedded in ECC matrix, and composite ECC material specimens (Li et al., 2004a). Specimens for both individual fiber pullout and composite ECC material were cured for 28 days at room temperature prior to immersion in hot water at 60°C for up to 26 weeks. After this exposure, little change was seen in fiber properties such as fiber strength, fiber elastic modulus, and elongation; however, the strain capacity of the ECC did drop from 4.5% at early age to 2.75%. Whereas the accelerated hot weather testing resulted in lower strain capacity of ECC, the 2.75% strain capacity (over 250 times that of normal concrete) seen after 26 weeks and equivalent to 70 years of natural weathering (Proctor et al., 1982) remains acceptable for most infrastructure applications.

24.5.2.4 Chloride Immersion

When ECC material is exposed to environments with high chloride concentrations, such as marine structures or for pavements and bridge decks subjected to deicing salt applications, chloride ions may alter the fiber–matrix interface and therefore the composite properties. To examine these effects, ECC coupon specimens were first preloaded under uniaxial tension to various strain levels, then exposed to a 3% NaCl solution at room temperature for 1, 2, and 3 months; they were then subsequently reloaded up to failure (Li et al., 2007). Figure 24.30 shows the data for the three sets of specimens preloaded to 0% (virgin), 0.5%, and 1.5% tensile strain. In all cases, the reloaded specimens retained multiple microcracking behavior and tensile strain capacity of more than 3%, although the average crack width increased from 40 μm to 100 μm and the tensile strength was reduced by about 10%. The wider crack width and lower tensile strength may be a result of a reduction in chemical bonding at the fiber–matrix interface, as suggested by single fiber pullout test data by Kabele et al. (2007).

24.5.2.5 Deicing Salt Exposure

Sahmaran and Li (2007) studied the durability performance of non-air-entrained ECC when subjected to mechanical loading and freezing and thawing cycles in the presence of deicing salts. After 50 exposure cycles, the surface condition visual rating and total mass of the scaling residue of ECC remained within acceptable limits according to ASTM C 672 (ASTM, 2003b) (Figure 24.31a). This level of durability held true even for specimens preloaded to cracking at high deformation levels. Non-air-entrained mortar specimens were used as reference specimens. As expected, these mortar prisms under identical testing conditions deteriorated severely. Preloaded and virgin (no preloading) ECC coupon specimens were also exposed to freezing and thawing cycles in the presence of deicing salts for 25 and 50 cycles to determine their residual tensile behavior. The reloaded specimens showed negligible loss of ductility but retained multiple microcracking behavior and a tensile strain capacity of more than 3% (Figure 24.31b). It was also found that multiple microcracks due to mechanical loading healed sufficiently under freezing and thawing cycles in the presence of salt solutions and restored the specimens to nearly the original stiffness. These results confirm that ECC, both virgin and microcracked, remains durable despite exposure to freezing and thawing cycles in the presence of deicing salts.

24.5.2.6 Alkali–Silicate Reaction Resistance

Sahmaran and Li (2008a) studied the resistance of ECC to alkali–silica reaction (ASR). ECC bar specimens were immersed in alkali solution at 80°C in accordance with ASTM C 1260 (ASTM, 2007) to determine their length change due to alkali silica reaction. The ECC bar specimens containing either Class F or Class C fly ash did not show any significant expansion at the end of a 30-day soaking period (Figure 24.32). Although very fine silica sand is used in ECC, the crystalline nature of these sand particles suppresses the reactivity in an alkaline environment. Further, the presence of a high volume of fly ash decreases the pH value due to the pozzolanic reaction, making alkali–silica reaction even less likely. Finally, the presence of the PVA microfibers tends to reduce any expansion that may occur. These studies show that ECC material will not exhibit degradation due to ASR.

24.5.3 Durability of R/ECC

Increased durability of reinforced concrete is typically associated with a dense concrete matrix—that is, a very compact microstructure expected to lower permeability and reduce transport of corrosives to the steel (Beeldens and Vandewalle, 2001; Oh et al., 2002). This can be achieved with a well-graded particle size distribution, fly ash and silica fume, or low W/C ratios. These concepts, however, rely upon the concrete remaining uncracked within a structure throughout its expected service life and resisting the transport of water, chloride ions, oxygen, etc. In this presumed uncracked state, numerous concrete materials have shown promising durability in laboratory tests (Mora et al., 2003; Weiss and Shah, 2002).

In reality, however, reinforced concrete members crack due to applied structural loads, shrinkage, chemical attack, and thermal deformations, which are practically inevitable and often anticipated in

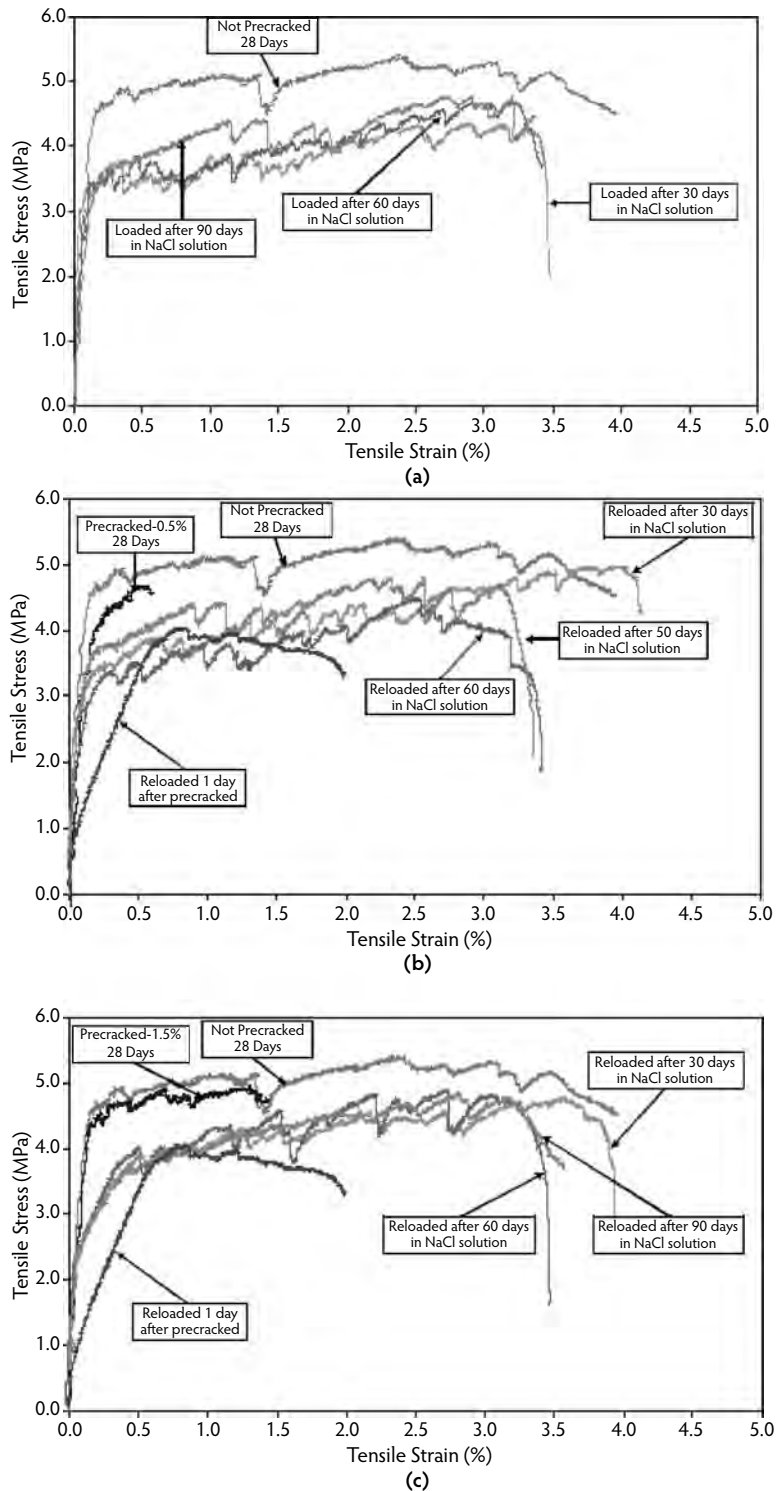

FIGURE 24.30 Tensile stress–strain curves of ECC: (a) virgin coupon specimens, (b) precracked (to 0.5%) specimens, and (c) precracked (to 1.5%) specimens, before and after being subjected to 3% NaCl solution exposure. (From Li, M. et al., in *Proceedings of the Fifth International RILEM Workshop on High-Performance Fiber-Reinforced Cement Composites (HPFRCC 5)*, Reinhardt, H.W. and Naaman, A.E., Eds., RILEM, Paris, 2007, pp. 313–322.)

FIGURE 24.31 Effect of freeze-thaw cycles in the presence of deicing salts for (a) beams preloaded to different bending deformation (BD) levels, showing mass of scaled-off particles, and (b) coupon specimens preloaded to different levels, showing uniaxial tensile stress-strain curves after 50 cycles of exposure. (From Sahmaran, M. and Li, V.C., *J. Cement Concrete Res.*, 37, 1035–1046, 2007.)

restrained conditions (Mihashi and De Leite, 2004; Wittmann, 2002). The durability of concrete is intimately related to its transport properties—that is, the rate at which corrosives and water are able to penetrate the concrete. This is because concrete is susceptible to degradation through leaching, corrosion, sulfate attack, freezing-and-thawing damage, and other mechanisms that depend on the ingress of water. Because cracks significantly modify the transport properties of concrete, their presence greatly accelerates the deterioration process. To solve this serious problem, a fundamental solution that reduces the brittle nature of concrete is needed.

The use of ECC to replace normal concrete in steel-reinforced concrete structures has a number of implications in terms of structural durability, including:

- Alteration of transport properties in the concrete or ECC cover, thereby delaying contact of aggressive agents with steel reinforcements through the intrinsic tight crack width control of ECC
- Alteration of the nature of steel corrosion with potentials for avoiding pitting and slowing the rate of corrosion through dispersed microcracking over a region of the steel reinforcement rather than concentrating at the base of a large crack and by its resistance to cover spalling via the tensile ductility of ECC

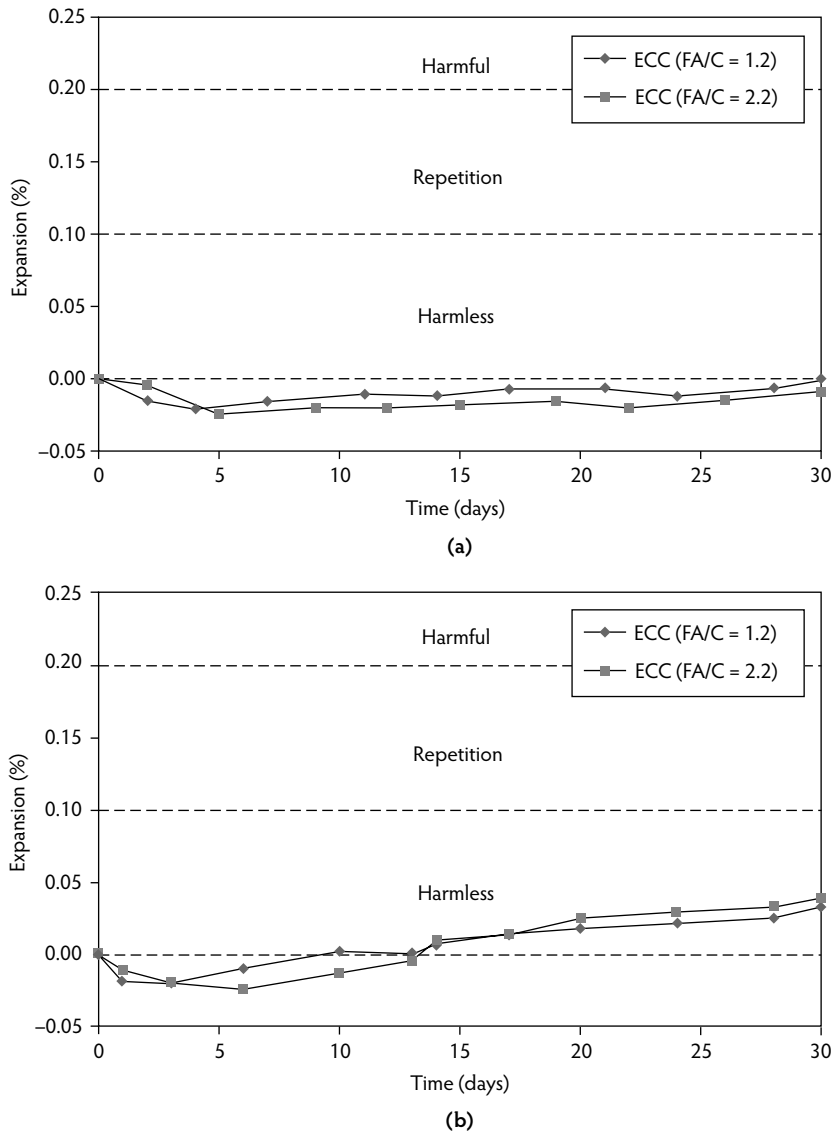

FIGURE 24.32 Length change of ECC mix with (a) Class F fly ash and (b) Class C fly ash subjected to alkali-silica reaction tests. (From Sahmaran, M. and Li, V.C., *J. Cement Concrete Composites*, 2008.)

These two alterations lead to expected improvements in structural durability due to a delay in the initiation phase of steel corrosion, and they dramatically slow the steel corrosion propagation phase. A number of experimental research efforts have been conducted that focus on the transport properties of ECC, especially when it is already in the strain-hardening stage with the presence of multiple microcracks, as well as on the behavior of steel-reinforced ECC elements in accelerated testing environments. Major findings of these two aspects are summarized in the following subsections. Recommendations for the design of R/ECC structures to protect against carbonation and chloride-ion-induced steel corrosion can be found in Rokugo et al. (2007).

24.5.3.1 Transport Properties of ECC

The most important transport properties of ECC include:

FIGURE 24.33 Permeability of precracked ECC and reinforced mortar measured as a function of crack width. (Adapted from Lepech, M.D. and Li, V.C., in *Proceedings of the 11th International Conference on Fracture (ICF XI)*, March 20–25, Torino, Italy, 2005.)

- Permeation in the presence of a hydraulic pressure, such as the condition in liquid containers and reservoir dams
- Diffusion in the presence of a ion concentration gradient, such as the condition on bridge decks, salt tanks, and marine environments
- Capillary suction induced by surface tension, of particular importance in ECC when crack width becomes very tight

All transport property tests described below were conducted at 28 days of age.

24.5.3.1.1 Water Permeation

Lepech and Li (2005a) found that cracked ECC exhibited nearly the same water permeability ($k \sim 5 \times 10^{-11}$ m/sec) as sound concrete, even when strained in tension to several percentage points (Figure 24.33). Within this study, both ECC and reinforced mortar specimens were pretensioned up to 1.5% deformation, resulting in a variety of crack widths and number of cracks among the various specimens. The permeability of these cracked materials was then determined under a hydraulic head. The dramatic rise in permeability with increasing crack width can be seen in the figure. For the ECC specimens, the crack width was intrinsically limited to about 60 μm (Section 24.2.2), regardless of the tensile deformation imposed; thus, the measured permeability was correspondingly low. Further, when normalized by number of cracks within the specimen, the comparable permeability of cracked ECC with sound material became even more apparent.

24.5.3.1.2 Chloride Diffusion

Chloride diffusion coefficients for ECC were examined by Sahmaran et al. (2007). Beam specimens were ponded in saltwater solution with 3% NaCl, according to AASHTO T259 (AASHTO, 2002). These measured values should really be regarded as the *effective chloride diffusion coefficient*, as the actual transport process is likely more complex than diffusion in a homogeneous medium without cracks. Based on tests on uncracked beams, the chloride diffusion coefficient for ECC was found to be 6.75×10^{-12} m²/sec, compared with 10.58×10^{-12} m²/sec based on tests on steel-reinforced mortar beams used as a control. Under high imposed bending deformation, preloaded ECC beam specimens revealed microcracks less than 50 μm and an effective diffusion coefficient significantly lower than that of similarly preloaded reinforced mortar control beams due to the tight crack widths inherent in ECC. In contrast, cracks larger than 150 μm were often produced under the same imposed deformation levels for the reinforced mortar

FIGURE 24.34 Diffusion coefficient vs. preloading deformation level for ECC and mortar. (From Sahmaran, M. et al., *ACI Mater. J.*, 104(6), 604–611, 2007.)

beams. Figure 24.34 shows the measured effective diffusion coefficient vs. preloading deformation level for ECC and mortar. It is revealed that the diffusion coefficient of ECC varies linearly with the number of cracks (with crack width being intrinsically constant even as beam deformation increases), whereas the diffusion coefficient of reinforced mortar is proportional to the square of the crack width. Chloride diffusion was also studied by Oh and Shin (2006) for specimens subjected up to 100,000 cycles of flexural loading. They found that the chloride diffusion coefficient did not increase significantly despite the increase number of cracks, and attribute this finding to the very fine crack width.

24.5.3.1.3 Capillary Suction

Sahmaran and Li (2008b) analyzed the water absorption and sorptivity properties of preloaded ECC, based on ASTM C 642 (ASTM, 2006) and ASTM C 1585 (ASTM, 2004) test procedures. Water absorption testing measures the mass of absorbed water per unit mass of the predried concrete material, after complete immersion in water until saturation is reached. Water absorption is expressed in terms of the volume percent of permeable pores. The sorptivity test measured the increase in mass of predried specimens at given intervals of time when permitted to absorb water by capillary suction in one direction, and it is quantified by the sorptivity index.

Figure 24.35 summarizes the findings of Sahmaran and Li which emphasized the impacts of the presence of microcracking and the water-repellent admixture on water absorption and sorptivity. From this figure, it can be seen that the presence of microcracks in ECC composites without water-repellent admixtures can lead to an exponential increase of the sorptivity index with the number of microcracks. However, sorptivity index values of cracked ECC are not particularly high when compared with those of normal concrete, probably due to the higher amount of cementitious materials, lower water/cementitious materials ratio, and high-volume fly ash content. For the ECC mixture with water-repellent admixtures, the presence of microcracks and their number had little or no effect on the sorptivity index. The water-repellent agent based on water-soluble silicon was very effective in reducing the sorptivity index of cracked ECC. ECC mixtures with water-repellent admixtures also showed lower percentages of permeable pores compared to the ECC mixtures without water-repellent admixture. In contrast to the sorptivity index, there was no significant influence of the number of cracks on the volume of permeable pores among the same ECC mixtures.

According to Neville (1995), the typical sorptivity index is $0.09 \text{ mm}/\text{min}^{1/2}$ for normal concrete with a W/C ratio of 0.4. Some other research studies suggested that ordinary Portland cement concrete with a W/C ratio of 0.4 to 0.5 would have a sorptivity index of about $0.23 \text{ mm}/\text{min}^{1/2}$ (Mehta and Monteiro, 2006). The sorptivity index for these cracked and virgin ECC specimens at a W/C ratio of 0.27 (especially

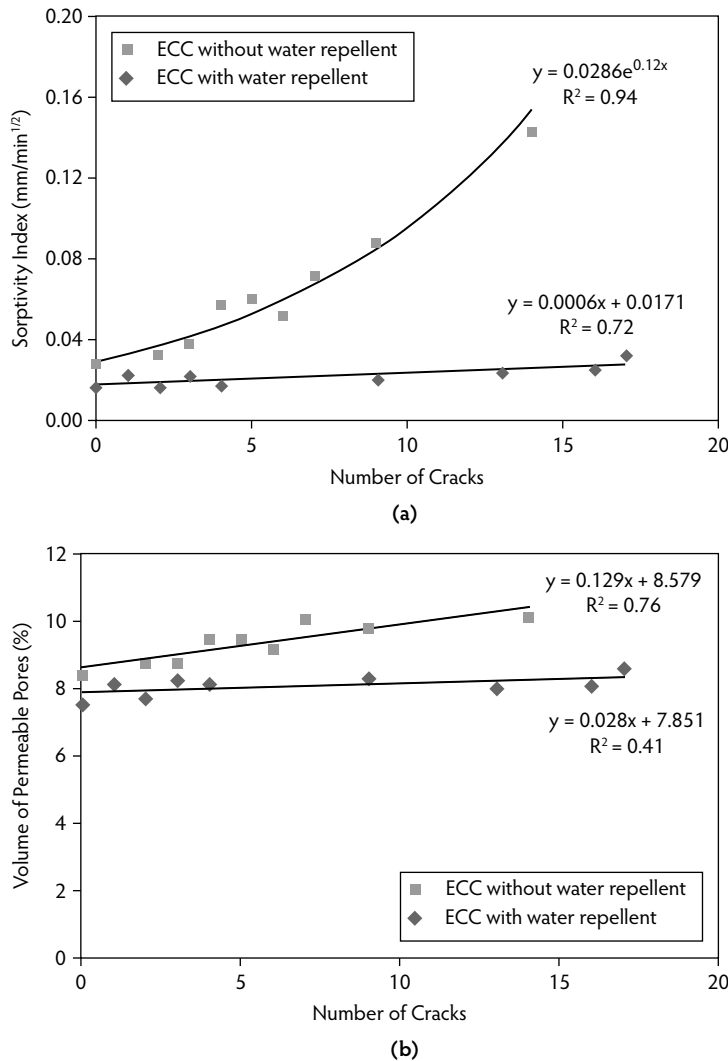

FIGURE 24.35 Capillary transport properties measured for preloaded ECC beams, showing the effects of water repellent on (a) sorptivity index and (b) volume of permeable pores as a function of the number of cracks. (From Sahmaran, M. and Li, V.C., *RILEM J. Mater. Struct.*, 2008.)

for those containing water-repellent admixtures, at about 0.02 to 0.03 mm/min^{1/2}) was significantly lower than that for conventional concrete. Water absorption tests by Mechtcherine and Lieboldt (2007) also confirmed that ECC strained to between 0.5 and 1% showed water-retardant ability. The findings by Sahmaran and Li (2008b), together with those of Mechtcherine and Lieboldt, confirm that capillary suction does not pose a danger to the durability of ECC structures despite the expected presence of fine cracks. This risk is further reduced by the use of water-repellent admixtures. These conclusions are consistent with the findings of Martinola et al. (2004).

24.5.3.2 Corrosion Resistance in R/ECC

From the discussions presented in Section 24.5.3.1, the transport properties of ECC associated with permeation under hydraulic gradient, diffusion under ion concentration gradient, or sorption and absorption under capillary suction, all show the tendency to improve over concrete and especially cracked concrete. Given that concrete structures are designed to allow some tensile cracking and that these cracks

FIGURE 24.36 Measured corrosion rate along the steel rebar for preloaded (a) R/C and (b) R/ECC. (Adapted from Miyazato S. and Hiraishi, Y., in *Proceedings of the 11th International Conference on Fracture (ICF XI)*, March 20–25, Torino, Italy, 2005.)

within reinforced concrete are typically the source of corrosion due to the increased transport of water and corrosives, there is substantial potential for ECC to improve the durability of R/C structures by acting as a quality cover where all transport mechanisms are substantially inhibited. The interaction between ECC and steel reinforcement from the viewpoint of corrosion resistance has been examined. The nature and rate of steel corrosion in ECC and the spall resistance of ECC when specimens are subjected to accelerated testing conditions are presented below.

24.5.3.2.1 Nature of Steel Corrosion

A study on chloride penetration rate and corrosion rate of steel reinforcement was carried out by Miyazato and Hiraishi (2005). Preloaded R/ECC and R/C beams were exposed to a 28-day accelerated chloride environment with wet cycles (saltwater shower, 90% relative humidity, 2 days) and dry cycles (60% relative humidity, 5 days). They found that chloride penetration reached 0 to 20 mm and 80 to 100 mm in the R/ECC and the R/C beams, respectively. The total (macro- and microcell) steel rebar corrosion rate was measured to be less than 0.0004 mm/year in the R/ECC but exceeded 0.008 mm/year in the R/C beams (Figure 24.36). The observed smaller chloride penetration depth is consistent with the smaller effective diffusion coefficient found by Sahmaran et al. (2007b) discussed in Section 24.5.3.1.2. The nature of corrosion in R/ECC is decidedly different from that in R/C. Microcell currents formed between the closely spaced microcracks in the R/ECC dominate macrocell currents so a greater length of steel reinforcement experiences corrosion in the R/ECC. The much higher rebar corrosion rate concentrated at the location of the concrete crack in the R/C specimen suggests a higher tendency for pitting corrosion of the steel reinforcement to occur.

24.5.3.2.2 Corrosion Propagation and Spall Resistance

Given the tensile ductility of ECC, the ability for the cover to remain intact despite steel corrosion serves as a possibility to further prolong the service life of R/ECC structures. Sahmaran et al. (2006a) investigated R/ECC beams subjected to accelerated corrosion by electrochemical method in studies designed to induce different degrees of corrosion into the reinforcement (a single steel rebar) embedded in ECC prismatic specimens. These experiments examined the spall resistance of R/ECC cover, the influence of an intact cover on the corrosion process in the corrosion propagation phase, the rate of loss of steel by corrosion, and the residual load capacity of R/ECC elements.

The corrosion-induced crack width of mortar specimens increased with time as corrosion activity progressed. Larger crack widths, up to 2 mm wide, were obtained at higher levels of corrosion. On the other hand, crack widths of ECC remained nearly constant (~0.1 mm) with time as corrosion activity progressed, while the number of cracks on the surface of the specimen increased. The results of this study

FIGURE 24.37 ECC and mortar specimens after accelerated corrosion test: (a) ECC prismatic specimen after 300 hours accelerated corrosion, (b) mortar prismatic specimen after 75 hours of accelerated corrosion, (c) ECC cylindrical specimen after 350 hours of accelerated corrosion, and (d) mortar cylindrical specimen after 95 hours of accelerated corrosion. (From Sahmaran, M. et al., *ACI Mater. J.*, 2008.)

also showed that ECC has significant anti-spalling capability as compared to conventional mortar (Figure 24.37). If a crack width of 0.3 mm, as specified by AASHTO (2004) for the maximum crack width limit for outdoor exposures, were used to represent the serviceability limit of reinforced concrete structures, the service life of reinforced ECC would be at least 15 times that of the reinforced mortar.

Reinforcement corrosion in mortar specimens resulted in a marked reduction in stiffness and flexural load capacity. After 25 hours of accelerated corrosion exposure, the flexural strength reduced to about 34% of the original flexural capacity of the control mortar beam. In contrast, the ECC specimens after 50 hours of accelerated corrosion exposure retained almost 100% of the original flexural capacity of the control specimens. Beyond 50 hours, the flexural capacity decreased but retained over 45% that of the control specimens even after 300 hours of accelerated corrosion exposure. Longitudinal cracks due to expansion of the corrosion products also affected the failure mode of the reinforced mortar under a four-point bend load (Figure 24.38). On the other hand, ECC deterioration due to the corrosion of reinforcement did not modify the type of failure in ECC beams.

FIGURE 24.38 Types of failure of reinforced mortar and ECC beams under four-point bending test for (a) ECC before accelerated corrosion, (b) ECC after 150 hours of accelerated corrosion, (c) mortar before accelerated corrosion, and (d) mortar after 50 hours of accelerated corrosion. (Adapted from Sahmaran, M. et al., *ACI Mater. J.*, 2008.)

The loss in load-carrying capacity is related to the mass loss of the steel reinforcement due to corrosion. The percentage of steel mass losses within the ECC and mortar beams throughout the accelerated corrosion process is presented in Figure 24.39. The average percentage of mass loss of steel reinforcing bars embedded in the mortar specimens were 2.5%, 5.3%, and 11.7% at the end of 25, 50, and 75 hours of accelerated corrosion tests, respectively. On the other hand, there was nearly no mass loss of steel reinforcing bars embedded in ECC specimens after up to 50 hours of accelerated corrosion testing, and the average percentage of mass loss of reinforcing bars embedded in ECC was 17.5% at the end of 300 hours of accelerated corrosion testing. The observed superior corrosion performance of ECC compared to mortar in terms of corrosion propagation time, tight crack width, lower weight loss, and higher retention of stiffness and flexural strength is attributable to the high tensile strain capacity, strain-hardening performance, and multiple cracking behavior of ECC. Overall, the experimental results from this study suggest that the propagation period of corrosion could be safely included in estimating the service life of a structure when concrete is replaced by ECC.

24.5.4 Long-Term Performance

The long-term performance of ECC in full-scale structures has not been fully established given the relatively recent development of this material; however, at least two field demonstration studies provide limited data supporting the contention that ECC can be durable under actual field conditions. One study (Rokugo et al., 2005) involves the use of ECC for repair of a concrete gravity earth-retaining wall (18 m wide by 5 m tall) that had been damaged by alkali-silica reaction (ASR) cracking. The decision to use ECC for the 50-

FIGURE 24.39 Mass loss vs. time for ECC and mortar corrosion specimens. (From Sahmaran, M. et al., *ACI Mater. J.*, 2008.)

to 70-mm-thick repair overlay was based on the need to prevent cracks in the substrate concrete from reflecting onto the repair layer. Such reflection was anticipated had normal concrete been used in this repair given continued ASR expansion. For demonstration, the wall was divided into nine repair blocks while a tenth block was left unrepaired. For the repaired blocks, two types of ECC—one containing 1.5% hybrid PVA and PE fibers (blocks 1 to 4) and another containing 2.1% PVA fibers (blocks 5 to 8)—were applied. In each block, welded wire mesh reinforcement, expanded metal reinforcement, or no reinforcement was used. For control, a welded wire mesh reinforced repair mortar was applied to block 9. Since 2003, when the repair took place, this wall has been continuously monitored. No cracking in the overlay was observed until 7 months after repair by ECC, while cracking was visually observed on the blocks repaired with normal mortar just 1 month after repair. The crack widths in the ECC repair blocks were less than 50 μm and 120 μm at 10 and 24 months, respectively. In contrast, the crack widths in the normal repair mortar block were 200 μm and 300 μm at 10 and 24 months, respectively. The crack patterns at 12 months and 24 months are shown in Figure 24.40. Another long-term performance verification is a small ECC patch repair placed on the bridge deck of Curtis Road over M-14 in Southern Michigan in 2002, in collaboration with the Michigan Department of Transportation (MDOT). A complete summary of this work has been outlined by Li and Lepech (2004). During this work, one section of a deteriorated bridge deck was repaired with ECC, while the remaining portion was repaired with a commercial concrete patching material commonly used by MDOT (Figure 24.41a). This repair scenario allowed for a unique comparison of ECC and concrete because both were subjected to identical environmental and traffic loads. (This road is used frequently by 11-axle trucks heavily loaded with aggregates, although it has a relatively low average daily traffic rate of 3000 vehicles/day.) The concrete repair material used was a prepackaged mixture of Portland cement and plaster of Paris. At this writing, the repaired bridge deck has experienced more than six complete Michigan winter cycles of freezing and thawing, in addition to live loads. The monitored crack width development is shown in Figure 24.41b. The ECC patch repair has survived this combined loading state with minor microcracking limited to less than 50 μm , but the concrete repair portion experienced cracking in excess of 3.5 mm and was repaired again in 2005.

24.6 Concluding Remarks

Engineered cementitious composite has a number of attractive properties. Most unique is the high tensile ductility several hundred times that of concrete with compressive strengths similar to concrete or high-strength concrete. The metal-like behavior of ECC is achieved without depending on high fiber content,

(a)

(b)

(c)

FIGURE 24.40 Cracking behavior of patched earth retaining wall: (a) Before repair, showing ASR damage; (b) after repair at 12 months; (c) after repair at 24 months. Blocks 1 to 8 used ECC, block 9 used a normal repair mortar, and block 10 was left unrepaired. (From Rokugo, K. et al., in *Proceedings of ConMat'05*, August 22–24, Vancouver, Canada, 2005.)

thus breaking the conventional wisdom of the need for a high fiber volume fraction to achieve high material performance. The moderate fiber content (2% or less by volume) makes ECC easily adaptable to construction project execution in the field or to precast plant structural element production. Indeed, ECC has demonstrated flexibility in processing routes, including on-site self-consolidating casting, and spraying, as well as off-site precasting and extrusion. Maintaining a moderately low fiber content is obviously important also for economic reasons (Li, 2004).

The large tensile ductility of ECC allows it to deform compatibly and creates a synergistic load-sharing capability with steel reinforcement in structural members. As a result, steel reinforcements in R/ECC members are better utilized in enhancing structural performance. Simultaneously, the tight crack width of ECC protects the steel reinforcement from typical corrosive processes, resulting in improved structural durability.

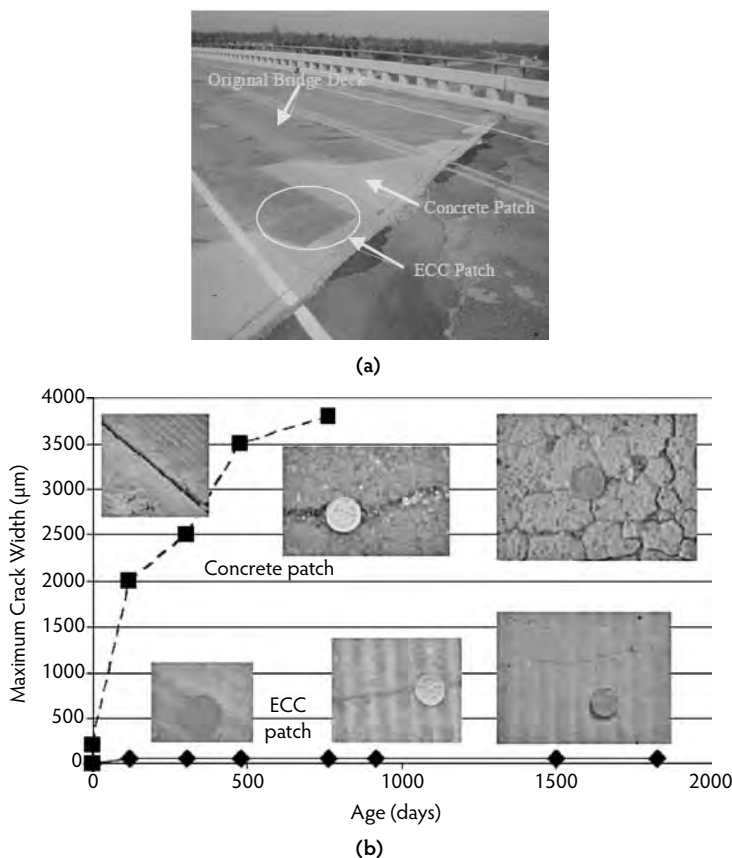

FIGURE 24.41 (a) ECC and concrete patches on the Curtis Road, Ann Arbor, MI, bridge deck; (b) maximum crack width development over time for the two materials. The concrete patch was re-repaired at about 1000 days.

In recent years, a number of full-scale applications of ECC have been carried out in various countries. Foremost among these is the use of ECC in precast R/ECC coupling beams in the core of two high-rises in Japan (Kunieda and Rokugo, 2006b; Maruta et al., 2005). This application exploits the high energy absorption capability of R/ECC to aid in the seismic resistance of these tall buildings. Other notable applications include cast-in-place ECC link slabs on bridge decks (Kim et al., 2004; Lepech and Li, 2005b) in the United States and Italy, a composite ECC/steel bridge deck in Japan (Mitamura et al., 2005), sprayed ECC tunnel linings in South Korea (Wonha, 2004), repair of the Mitaka Dam in Japan (Kojima et al., 2004), an irrigation channel repair in Japan (Kunieda and Rokugo, 2006b), and prototype pipe extrusion in Australia. Several projects in the housing and energy industries employing ECC are in various planning stages. Despite the advanced stage of development of ECC and its application readiness, a great deal of research and experimentation remain to be done. Indeed, the transformation of brittle concrete to ductile ECC offers enormous opportunities in structural innovations not possible previously.

Although safety and durability are critically important in any successful engineering project, concerns for infrastructure sustainability are growing due to greater recognition of the impact of the built environment on the natural environment. Green ECC employing industrial byproducts as components is being developed (Lepech and Li, 2008; Li et al., 2004b; Yang et al., 2007). Combined with the greater durability of ECC, such advancements offer a way to reduce environment burdens due to transportation infrastructures such as bridges and pavements (Keoleian et al., 2005; Lepech, 2006; Li et al., 2008). Sustainable infrastructures are critical to sustainable economic development in developed and developing countries. Materials technological advancements must contribute to this worldwide effort.

Acknowledgments

The author would like to acknowledge the research support of the National Science Foundation (the Biocomplexity, the Cyberinfrastructure, and the Civil, Mechanical and Manufacturing Innovation programs) and the Michigan Department of Transportation. Many former and current students, postdoctorates, and colleagues at the University of Michigan contributed to this work. Their devotion to advancing infrastructure materials is greatly appreciated. Knowledge on ECC has been greatly expanded by the intense research activities of many academic and industrial groups around the world in the last several years. Special thanks are extended to Dr. M. Lepech who reviewed a draft of this manuscript and provided helpful suggestions for improvements.

25.1 Introduction

The design of concrete members either reinforced with FRP reinforcing bars or strengthened with strips or sheets of FRP laminates or fabrics is discussed in this chapter. The discussion in this chapter follows the design recommendations of the most current versions of the design guidelines published by the American Concrete Institute (ACI) that are used to design these concrete structures in the United States. The material presented is an updated and expanded version of portions of the chapter Fiber-Reinforced Polymer Composites, which appeared in the *Handbook of Structural Engineering* (Bank, 2004) and was based on ACI design guidelines in 2003. In addition, this chapter is intended to provide a brief overview of topics covered in greater detail and accompanied by illustrative examples in *Composites for Construction: Structural Design with FRP Materials* (Bank, 2006.) Research in the use of FRP reinforcements and FRP strengthening systems for concrete structures has been the focus of intense international research activity since the late 1980s. A biannual series of symposia entitled *Fiber-Reinforced Plastics in Reinforced Concrete Structures* (FRPRCS) has been the leading venue for reporting and disseminating these research results. The most recent symposium, the seventh in the series dating back to 1993, was held in Patras, Greece, in 2007 (Triantitillou, 2007).

* Professor, Civil and Environmental Engineering, at the University of Wisconsin, Madison; expert in the mechanics and design of composite material structures with an emphasis on applications to civil engineering.

FIGURE 25.1 Typical FRP reinforcing bars for concrete members.

25.2 Design of FRP-Reinforced Concrete Members

25.2.1 Introduction

Fiber-reinforced polymer (FRP) reinforcing bars and grids have been commercially produced for reinforcing concrete structures for over 30 years (ACI Committee 440, 1996; Bank, 2006; Nanni, 1993). FRP reinforcing bars have been developed for prestressed and non-prestressed (conventional) concrete reinforcement. This section considers only non-prestressed reinforcement for concrete structures and follows the procedures of ACI 440.1R-06, *Guide for the Design and Construction of Structural Concrete Reinforced with FRP Bars* (ACI Committee 440, 2006). Note that ACI 440.1R-06 does not cover reinforcing with prefabricated FRP grids and mats. Recommendations for the design of prestressed FRP-reinforced concrete can be found in ACI 440.4R-04, *Prestressing Concrete with FRP Tendons* (ACI Committee 440, 2004b). Current FRP reinforcing bars (referred to as FRP rebars in what follows) are commercially produced using thermosetting polymer resins (commonly, polyester and vinylester) and glass, carbon, or aramid reinforcing fibers. The most common bars produced today are glass-fiber-reinforced vinylester bars. These are recommended for use in reinforcing applications for load-bearing concrete structures. The bars are primarily longitudinally reinforced with volume fractions of fibers in the range of 50 to 60%. FRP reinforcing bars are usually produced by a process similar to pultrusion (Starr, 2000) and have a surface deformation or texture to develop the bond to concrete. More information on the historical development, constituent materials, and manufacturing processes of FRP rebars can be found in Bank (2006). A photograph of some typical FRP reinforcing bars is provided in Figure 25.1. In addition to the ACI design guidelines, a number of other design guides have been published for FRP-reinforced concrete. These include Japanese (BRI, 1995; JSCE, 1997) and Canadian (ISIS, 2001; CSA, 2002) guides.

25.2.2 Properties of FRP Reinforcing Bars

Glass-fiber-reinforced vinylester bars are available from a number of manufacturers in the United States, Europe, and Asia. Bars are typically produced in sizes ranging from 3/8 in. in diameter to 1-1/4 in. in diameter (i.e., #3 to #10 bars.) FRP bars have a non-smooth surface, which is required for bond to the concrete (see Figure 25.1) and is typically produced by a sand-coated external layer, molded deformations, machined ribs, or a spiral wind. The properties of FRP rebars are intended to be measured and reported by FRP rebar manufacturers in accordance with ACI 440.3R-04, *Guide Test Methods for Fiber-Reinforced Polymers (FRP) for Reinforcing or Strengthening Concrete Structures* (ACI Committee 440, 2004a). A standard product specification for FRP rebars has recently been approved for publication by the Canadian Standards Organization (ISIS, 2006). The ACI is currently preparing a standard specification

TABLE 25.1 Properties of Typical Commercially Produced FRP Reinforcing Bars

	Glass-Reinforced Vinylester Bar ^{a,b,c} (0.5-in. Diameter)	Glass-Reinforced Vinylester Bar ^a (1-in. Diameter)	Carbon-Reinforced Vinylester Bar ^a (0.375-in. Diameter)	Carbon-Reinforced Epoxy Bar (0.5-in. Diameter)
Fiber volume (estimated)	50–60	50–60	50–60	50–60
Fiber architecture	Unidirectional	Unidirectional	Unidirectional	Unidirectional
<i>Strength</i> ($\times 10^3$ psi)				
Tensile, longitudinal	90–100	80	300	327
Compressive, longitudinal	NR	NR	NR	NR
Bond strength	1.7	1.7	1.3	NR
Shear, out-of-plane	22–27	22	NR	NR
<i>Stiffness</i> ($\times 10^6$ psi)				
Tensile, longitudinal	5.9–6.1	5.9	18	21.3
Compressive, longitudinal	NR	NR	NR	NR
CTE, longitudinal ($10^{-6}/^{\circ}\text{F}$)	3.7–4.9	3.7	–4.0–0	0.38
CTE, transverse ($10^{-6}/^{\circ}\text{F}$)	12.2–18.7	18.7	41–58	NR
Barcol hardness	60	60	48–55	NR
24-hour water absorption (% max.)	NR	NR	NR	NR
Density (lb/in. ³)	0.072	0.072	NR	0.058

^a Data for Aslan® (Hughes Brothers, Seward, Nebraska).

Note: CTE, coefficient of thermal expansion; NR, not reported by the manufacturer.

for FRP bars. For design, the key mechanical properties of interest are the longitudinal tensile strength and longitudinal tensile modulus of the bar. Most FRP bars are brittle and exhibit strongly linear and elastic axial stress–strain or axial load–deformation characteristics up to their failure loads. They do not yield and have no plastic deformation capacity as do steel rebars. It is also important to note that, unlike steel rebars, the longitudinal strength (but not the longitudinal modulus) of FRP rebars decreases with the diameter of the bar. This is attributed to the relatively low in-plane shear modulus of FRP rebars (leading to shear lag effects), the additives used to produce larger diameter bars, and a statistical size effect in brittle glass fibers. Designers should always consult the manufacturer’s published properties for use in design. Typical properties for glass-fiber FRP rebars and carbon-fiber FRP bars are provided in Table 25.1. It should be noted that the carbon-fiber bars are typically used as prestressing tendons or *near-surface-mounted* (NSM) strengthening rods and not as conventional reinforcing bars due to cost considerations.

Fiber-reinforced polymer rebars are considered to be transversely isotropic from a mechanics perspective (Bank, 1993). Theoretical equations are available to predict the mechanical and physical properties of the FRP rebars from the properties of the fiber and resin constituents; however, for design purposes, measured properties of the as-produced bars must be used. At this time, theoretical methods are not yet available to predict the bond properties and the long-term durability characteristics of FRP rebars. Test methods for determining and reporting the alkali resistance, creep, and fatigue characteristics of FRP rebars are provided in ACI 440.3R-04 (ACI Committee 440, 2004a). FRP rebars containing glass fibers can fail catastrophically under sustained loads at stresses lower than their tensile strengths, a phenomenon known as *creep rupture* or *static fatigue*. Design guides therefore limit the amount of sustained load on concrete structures reinforced with FRP rebars.

Fiber-reinforced polymer rebars should only be used at service temperatures below the glass transition temperature (T_g) of the polymer resin system used in the bar. For typical vinylester polymers, this is around 200°F. The bond properties have been shown to be highly dependent on the glass transition temperature of the polymer. In addition, it is important to note that the coefficients of thermal expansion of FRP rebars are not the same in the transverse (radial) direction as in the longitudinal direction. The coefficient of thermal expansion may be close to an order of magnitude higher in the transverse direction

of the bar due to its anisotropic properties (see typical properties in Table 25.1). This may cause longitudinal splitting in the concrete due to temperature and shrinkage effects if sufficient cover is not provided.

Fiber-reinforced polymer reinforcing bars made of thermosetting polymers cannot be bent in the field and must be produced by the FRP rebar manufacturer with bends for anchorages or for stirrups. The strength of the FRP rebar at the bend is substantially reduced and must be considered in the design. According to ACI 440.1R-06, FRP rebars should not be used for carrying compressive stress in concrete members (i.e., compression reinforcement in beams or columns) as this time, as insufficient research has been conducted on this topic. Where FRP bars are used in the compression zone they should be suitably confined to prevent local instability.

25.2.3 Design Basis for FRP-Reinforced Concrete

The *load and resistance factor design* (LRFD) basis is stipulated by ACI 440.1R-06, which provides the resistance factors (ϕ , or phi factors) for use with FRP rebars that are calibrated for the load factors required for use in design with conventionally reinforced concrete structures by ACI 318-05 (e.g., 1.2 for dead load and 1.6 for live load) (ACI Committee 318, 2005). For the design of flexural members reinforced with FRP rebars, ACI 440.1R-06 provides the following resistance factors:

Flexural capacity (tensile reinforcement only):

$\phi = 0.55$ for an under-reinforced beam section ($\rho_f < \rho_{fb}$).

$\phi = 0.65$ for a substantially over-reinforced beam section ($\rho_f > 1.4\rho_{fb}$).

$\phi = 0.3 + 0.25\rho_f/\rho_{fb}$ for a lightly over-reinforced beam section ($\rho_{fb} < \rho < 1.4\rho_{fb}$).

Shear capacity (FRP shear reinforcement in the form of stirrups):

$\phi = 0.75$ per ACI 318-05.

where ρ_f is the FRP reinforcement ratio and ρ_{fb} is the balanced FRP reinforcement ratio. The FRP reinforcement ratio for an FRP-reinforced rectangular beam section (where the subscript f is used to indicate FRP reinforcement to distinguish it from conventional reinforcement) is given as:

$$\rho_f = \frac{A_f}{bd} \quad (25.1)$$

and the balanced FRP reinforcement ratio is given as:

$$\rho_{fb} = 0.85\beta_1 \frac{f'_c}{f_{fu}} \frac{E_f \epsilon_{cu}}{E_f \epsilon_{cu} + f_{fu}} \quad (25.2)$$

where A_f is the area of FRP reinforcement, b is the beam width, d is the effective depth, β_1 is a factor that depends on concrete strength (e.g., 0.85 for 4000-psi concrete), f'_c is the cylinder compressive strength of the concrete, E_f is the longitudinal modulus of the FRP rebar, ϵ_{cu} is the nominal ultimate compressive strain in the concrete (taken as 0.003), and f_{fu} is the longitudinal design strength of the FRP rebar. Figure 25.2 shows the distribution of strains, stresses, and forces at the service condition and at the ultimate condition for an FRP reinforced section.

The design strength (f_{fu}) and design failure strain (ϵ_{fu}) are obtained from the manufacturer-reported guaranteed strength and guaranteed failure strain by multiplying them by an *environmental reduction factor* (C_E), which depends on the fiber type in the bar and the type of intended service of the structure. For example, for glass FRP rebars, C_E is 0.7 for exterior concrete and 0.8 for interior concrete. The guaranteed strength and guaranteed strain to failure of FRP rebars are defined as the mean minus 3 standard deviations of a minimum of 25 test samples (ACI Committee 440, 2006).

In addition to the strength criteria described above, the design basis for FRP-reinforced concrete members also includes stipulations on the behavior and appearance of the FRP-reinforced member under service

FIGURE 25.2 Strains, stresses, and forces in the FRP-reinforced section at service and ultimate loads.

loads. Maximum flexural crack widths are limited to 0.20 and 0.28 mils for exterior and interiors exposure, and the stress in the main FRP reinforcing bars is limited to $0.2f_{fu}$, $0.3f_{fu}$, and $0.55f_{fu}$ for glass, aramid, and carbon bars, respectively, to prevent failure under sustained loads due to creep rupture or due to fatigue. Because FRP rebars typically have a lower modulus than steel rebars, the serviceability criteria (typically, deflections and crack widths) can often control the design of FRP-reinforced concrete sections.

25.2.4 Design of Flexural Members with FRP Reinforcing Bars

25.2.4.1 Flexural Capacity with FRP Main Tension Bars

The nominal moment (or flexural) capacity of an FRP-reinforced concrete member (such as a beam or a slab) is determined in a manner similar to that of a steel-reinforced section. However, because FRP rebars do not yield, the ultimate strength of the bar replaces the yield strength of the steel rebar in the traditional concrete beam design formula based on strain compatibility (assuming plane sections remain plane and bars are perfectly bonded to the concrete) and equilibrium of forces. Both under-reinforced section design and over-reinforced section design are permitted; however, due to serviceability limits (primarily long-term deflections and crack widths), most glass FRP-reinforced flexural members will be over-reinforced.

When $\rho_f > \rho_{fb}$, the over-reinforced section will fail due to concrete crushing, and the nominal moment capacity is given in a manner similar to that for a section reinforced with steel rebars (where the rebar has not reached its yield stress). The stress in the rebar therefore must be calculated to determine the capacity of the section. The nominal moment capacity is given as:

$$M_n = A_f f_f \left(d - \frac{a}{2} \right) \quad (25.3)$$

where:

$$a = \frac{A_f f_f}{0.85 f'_c b} \quad (25.4)$$

$$f_f = \left(\sqrt{\frac{(E_f \epsilon_{cu})^2}{4} + \frac{0.85 \beta_1 f'_c}{\rho_f} E_f \epsilon_{cu}} - 0.5 E_f \epsilon_{cu} \right) \quad (25.5)$$

where f_f is the stress in the FRP rebar at concrete compressive failure, and a is the depth of the equivalent rectangular (Whitney) stress block in the concrete.

When $\rho_f < \rho_{fb}$, the under-reinforced section will fail due to rupture of the FRP rebars in tension. Because the FRP reinforcement will not yield prior to its failure, the moment capacity of the section cannot be calculated assuming the concrete crushes when the bar ruptures (as in the case of a steel under-reinforced section). For this reason, the section capacity should be calculated using appropriate non-linear stress-strain relations of the concrete; however, this requires an iterative solution procedure, which is not suited to design calculations. To overcome this situation, ACI 440.1R-06 recommends computing the approximate (and conservative) nominal flexural capacity as:

$$M_n = A_f f_{fu} \left(d - \frac{\beta_1 c_b}{2} \right) \quad (25.6)$$

where c_b is the depth of the neutral axis at the balanced reinforcement ratio, given as:

$$c_b = \left(\frac{\epsilon_{cu}}{\epsilon_{cu} + \epsilon_{fu}} \right) d \quad (25.7)$$

A minimum amount of flexural reinforcement should be provided when the FRP-reinforced beam is designed to fail by FRP bar rupture to prevent failure at concrete cracking. The amount is given as:

$$A_{f,min} = \frac{4.9 \sqrt{f'_c}}{f_{fu}} b d \geq \frac{330}{f_{fu}} b d \quad (25.8)$$

25.2.4.2 Shear Capacity with FRP Main Tension Bars and FRP Shear Reinforcement

The nominal shear capacity of an FRP-reinforced concrete member loaded in flexure is influenced by the mechanical properties of the FRP main tension reinforcing bars and by FRP shear reinforcement, which is typically supplied in the form premanufactured stirrups. The lower modulus of the FRP main bars (assuming glass fibers) leads to a shallower compression zone and larger deflections at flexural failure of FRP-reinforced flexural members than would be obtained in the same section reinforced with steel bars. In addition, the strain in the FRP stirrups is limited to prevent large shear cracks from developing in the FRP-reinforced concrete member. Added to this, the strength of the FRP bar is reduced when it is bent to form a stirrup due to the linear elastic material properties and the manufacturing process used to manufacture bent FRP bars.

The nominal shear capacity (V_n) of an FRP-reinforced concrete beam is:

$$V_n = V_c + V_f \quad (25.9)$$

where V_c is the nominal shear capacity of the concrete with FRP rebars used as main tension reinforcement and is given as:

$$V_c = 5 \sqrt{f'_c} b_w c \quad (25.10)$$

where b_w is the width of the beam web, and c is the depth of the neutral axis in the cracked elastic section as defined for the serviceability calculations and is given as:

$$c = k d \quad (25.11)$$

$$k = \sqrt{(\rho_f \eta_f)^2 + 2 \rho_f \eta_f} - \rho_f \eta_f \quad (25.12)$$

$$\eta_f = \frac{E_f}{E_c} \quad (25.13)$$

where η_f is the modular ratio, k is the depth ratio, and V_f is the nominal shear capacity provided by the FRP stirrups. For vertical FRP shear stirrups, it is given as:

$$V_f = \frac{A_{fv} f_{fv} d}{s} \quad (25.14)$$

where A_{fv} is the total area of the stirrups that cross the shear crack, and f_{fv} is the strength of the FRP stirrup, which is limited by the smaller of:

$$f_{fv} = 0.004 E_f \quad (25.15)$$

and the strength of the FRP rebar at its bend:

$$f_{fb} = \left(0.05 \frac{r_b}{d_b} + 0.3 \right) f_{fu} \quad (25.16)$$

where f_{fb} is the strength of the FRP rebar at its bend, r_b is the inside radius of the bend, and d_b is the diameter of the FRP rebar. Standard bend radii are reported by manufacturers and range from 4.25 to 6 in. for typical FRP rebars. The ratio of r_b/d_b may not be less than 3.

25.2.4.3 Design for Serviceability

For serviceability design of concrete members with FRP bars three criteria, all calculated with respect to the service loads on the member (with no load factors applied), must be checked against code-stipulated limits provided in ACI 440.1R-06: (1) maximum crack widths due to all loads, (2) maximum short-term and long-term deflections due to all loads accounting for long-term creep effects, and (3) maximum stresses in the FRP bars due exclusively to sustained loads and fatigue. The width of a flexural crack in an FRP-reinforced member is calculated from:

$$w = 2 \frac{f_f}{E_f} \beta k_b \sqrt{d_c^2 + \left(\frac{s}{2} \right)^2} \quad (25.17)$$

where w is the crack width (in inches), f_f is the service load stress in the FRP reinforcement (in ksi), E_f is the modulus of the FRP rebars (in ksi), β is the ratio of the distance between the neutral axis and the bottom of the section (i.e., the tension surface) and the distance between the neutral axis and the centroid of reinforcement, d_c is the thickness of the concrete cover from the tension face to center of the closest bar (in inches), s is the center-to-center bar spacing of the main FRP bars (in inches), and k_b is a bond-related coefficient. k_b is taken as 1.4 for commercially produced FRP rebars. β is determined from:

$$\beta = \frac{h - kd}{d(1 - k)} \quad (25.18)$$

where h is the section depth and d is the effective section depth. The stress in the FRP bar at service loads can be calculated from:

$$f_{f,s} = \frac{m_s \eta_f d (1 - k)}{I_{cr}} \quad (25.19)$$

where m_s is the service load moment.

To calculate maximum short-term and long-term deflections under service loads, a modified form of the Branson equation is used:

$$I_e = \left(\frac{M_{cr}}{M_a} \right)^3 \beta_d I_g + \left[1 - \left(\frac{M_{cr}}{M_a} \right)^3 \right] I_{cr} \leq I_g \quad (25.20)$$

where I_e is the effective second moment of area of the cracked section, I_g is the second moment of the gross section, M_{cr} is the moment at cracking, M_a is the applied service load moment, and β_d is a reduction coefficient for FRP reinforced beams that is given as:

$$\beta_d = \frac{1}{5} \left(\frac{\rho_f}{\rho_{fb}} \right) \leq 1.0 \quad (25.21)$$

As in conventional steel-reinforced concrete, the cracked (transformed to concrete) second moment of the section is given as:

$$I_{cr} = \frac{bd^3}{3} k^3 + \eta_f A_f d^2 (1-k)^2 \quad (25.22)$$

The long-term deflections, including the effects of creep and shrinkage of the concrete under the sustained long-term service loads (i.e., the dead load and the sustained live load), can be calculated as:

$$\Delta_{(cp+sh)} = 0.6\xi(\Delta_i)_{sus} \quad (25.23)$$

where $(\Delta_i)_{sus}$ is the short-term (or instantaneous) deflection due to the sustained loads only and is calculated using the modified Branson formula; $\xi = 2.0$ for sustained loads with a duration of 5 years or more as per ACI 318-05 (ACI Committee 318, 2005).

All FRP-reinforced concrete beams must be checked for possible failure due to creep rupture or fatigue under service loads. Creep rupture is checked with respect to all sustained service loads, whereas fatigue is checked with respect to all sustained loads plus the maximum moment induced in a fatigue loading cycle:

$$f_{f, \text{ creep rupture}} = \frac{m_{sus} \eta_f d (1-k)}{I_{cr}} \quad (25.24)$$

where m_{sus} is the moment due to the sustained service loads.

25.2.4.4 Detailing of FRP Reinforcements

The development length of an FRP rebar is different from the development length of a conventional steel rebar. In addition, a beam reinforced with FRP bars can potentially fail due to splitting bond failure between the FRP bar and the concrete due to the high tensile stress that can be developed in FRP bars. The required development length (ℓ_d) for a straight FRP bar is given as:

$$\ell_d = \frac{\alpha \frac{f_{fr}}{\sqrt{f'_c}} - 340}{13.6 + \frac{C}{d_b}} (d_b) \quad (25.25)$$

where f_{fr} is the stress in the FRP bar at failure which is the lesser of (1) the design strength of the bar for under-reinforced beams (f_{fu}), (2) the actual stress in the bar for over-reinforced sections (f_f), or (3) the effective bond critical design stress in the bar for both over and under-reinforced sections (f_{fe}), which is given as:

$$f_{fe} = \frac{\sqrt{f'_c}}{\alpha} \left(13.6 \frac{\ell_e}{d_b} + \frac{C}{d_b} \frac{\ell_e}{d_b} + 340 \right) \leq f_{fu} \quad (25.26)$$

where C is the lesser of (1) the distance from the center of the bar to the nearest outer concrete surface in the tension zone, or (2) half the on-center spacing of the bars (side-by-side); α is the bar location factor, which is taken as 1.0 for bars that are in the bottom 12 in. of the formwork when the concrete is cast and as 1.5 when the bars are more than 12 in. above the bottom of formwork when the beam is cast (known as *top-bars*). ACI 440.1R-06 further recommends that the term C/d_b not be taken as larger than 3.5 and that the minimum embedment length (ℓ_e) be at least 20 bar diameters, or $20d_b$.

For hooked bars, the development length of the portion extending beyond the bend (the tail length) is given as a function of the FRP rebar design strength. For FRP rebars with design strengths in the range of 75 to 150 ksi (typical of glass FRP rebars), the length of the hook (l_{bhf}) is given as:

$$l_{bhf} = \frac{f_{fu}}{37.5} \frac{d_b}{\sqrt{f'_c}} \quad (25.27)$$

It should not be less than $12d_b$ or 9 in. Tension lap splices for FRP rebars are based on recommendations for steel rebars and limited test data. For Class A and Class B lap splices, the recommended develop lengths are $1.3l_{df}$ and $1.6l_{df}$, respectively. FRP stirrups can be spaced at a maximum of $d/2$ (or 24 in.) and should have a minimum r_b/d_b ratio of 3. The tail length of 90° hooks in the stirrups must be at least $12d_b$.

25.3 Design of FRP-Strengthened Concrete Members

25.3.1 Introduction

Fiber-reinforced polymer reinforcing systems for strengthening structurally deficient concrete structural members and for repairing damaged or deteriorated concrete structures have been used since the mid-1980s (Bank, 2006). This section provides guidance for the design of FRP strengthening systems according to the procedures of ACI 440.2R-02, *Guide to the Design and Construction of Externally Bonded FRP Systems for Strengthening Concrete Structures* (ACI Committee 440, 2002). This guide is used for the design of most FRP strengthening systems currently designed in the United States. This guide is still based on ACI 318-99 load factors (e.g., 1.4 for dead loads and 1.7 for live loads). It is currently under revision and, in addition to other changes, the next edition will be compatible with ACI 318-05 load factors (e.g., 1.2 for dead loads and 1.6 for live loads). The reader is advised to consult the new version of this guide when it is released in 2008.

The first FRP-strengthened concrete structures were beams strengthened to increase their flexural capacity using high-strength, lightweight, carbon-fiber-reinforced epoxy laminates that were bonded to the undersides of the beams. The method is a modification of one where epoxy-bonded steel plates are used to strengthen concrete beams which has been in use since the mid-1960s. The FRP systems were shown to provide significant benefits in constructability and durability over the steel plates. Thereafter, significant work was conducted on strengthening of concrete columns to enhance their axial capacity, shear capacity, and ductility, primarily for seismic loadings. This method is a modification of one using steel jackets to strengthen concrete columns. This was followed closely by work on shear strengthening of beams. A review of the state of the art on the subject can be found Teng et al. (2001), Hollaway and Head (2001), and Bank (2006). The method has also been used to strengthen masonry and timber structures; however, applications of this type are not discussed in this chapter.

Current FRP strengthening systems for concrete fall into two popular types: *precured* and *formed-in-place* systems. The precured systems consist of factory manufactured laminates (known as *strips* or *plates*) of carbon-or glass-reinforced thermosetting polymers (typically epoxy or vinylester) that are bonded to the surface of the concrete using an epoxy adhesive. The manufactured precured laminates typically have

FIGURE 25.3 Typical FRP strengthening systems for concrete members.

a volume fraction of fibers in the range of 55 to 65% and are cured at high temperatures ($>300^{\circ}\text{F}$) but are bonded in the field at ambient temperatures. The formed-in-place systems consist of layers of unidirectional sheets or woven or stitched fabrics of dry fibers (usually glass, carbon, or aramid) that are saturated in the field with a thermosetting polymer (e.g., epoxy or vinylester) which simultaneously produces and bonds the FRP material to the concrete. The process is often referred to as *lay-up*. The formed-in-place FRP systems typically have a fiber volume fraction of between 20 and 40% and are cured at ambient temperatures in the field. Figure 25.3 shows a number of currently produced FRP strengthening systems.

A number of design guides and national standards are currently published that provide recommendations for the analysis, design, and construction of concrete structures strengthened with FRP materials (Concrete Society, 2004; CSA, 2002; FIB, 2001; ICC Evaluation Service, 1997; JSCE, 2001). In addition, manufacturers of FRP strengthening systems for concrete typically provide their own design and installation guides for their proprietary systems. Because the performance of the FRP strengthening system is highly dependent on the adhesive or saturating polymer used, the preparation of the concrete surface prior to application of the FRP strengthening system, and the field installation and construction procedures, manufacturers frequently certify *approved contractors* to ensure that their systems are designed and installed correctly. Guidance to ensure that FRP strengthening systems are appropriately installed, monitored, and inspected is provided in a number of guides (Concrete Society, 2003; ICC Evaluation Service, 2001; TRB, 2004).

25.3.2 Properties of FRP Strengthening Systems

Carbon-fiber-reinforced epoxy laminates (or strips) are the most commonly used of the precured FRP strengthening systems. Depending on the type of carbon fiber used in the strip, different longitudinal strengths and stiffness are produced. Strips are typically thin (less than 0.100 in.) and are available in a variety of widths (typically 2 to 4 in.). Because the strips are reinforced with unidirectional fibers, they are highly orthotropic with very low properties in the transverse and through the thickness directions. Manufacturers typically only report properties in the longitudinal directions and report very little data on physical properties. The strips are bonded to the concrete with an adhesive that is supplied by the strip manufacturer. Typical properties of strips are shown in Table 25.2. It is important to note that the properties shown for the strips are properties of the FRP composite and not the properties of the fibers alone.

In the formed-in-place FRP strengthening systems, a greater array of products is available depending on fiber type and sheet or fabric architecture. In this group of products, a unidirectional, highly orthotropic carbon-fiber *tow sheet* is produced by a number of manufacturers and is often used in strengthening

TABLE 25.2 Properties of Typical Commercially Produced FRP Strengthening Strips

	Standard-Modulus Carbon-Reinforced Epoxy Strip ^{a,b,c}	High-Modulus Carbon-Reinforced Epoxy Strip ^a	Glass-Reinforced Epoxy Strip ^b	Carbon-Reinforced Vinylester Strip ^d

applications. The individual carbon tows in the sheet are held together by a polymeric binder (or a light stitching). The sheet is often supplied on a wax paper backing. Sheets are typically 10 to 40 inches wide and can be applied in multiple layers with different orientations. The common fabric materials in the formed-in-place group are woven or stitched fiber fabrics having an areal density of 12 to 32 oz/yd². Carbon-fiber fabrics and hybrid fabrics (with more than one fiber type) are also available. Fabrics are typically much thicker than tow sheets. They are also used in multiple layers. Because of the wide variety of products available and their different thicknesses, it is not easy to compare their properties directly. In addition, the fibers must be used with a compatible resin system applied at a controlled volume fraction to achieve a FRP composite with desirable properties. In the case of sheet and fabric materials, manufacturers typically report the mechanical properties of the dry fibers and the thickness (or area) of the fibers. It is important to note that when reported in this fashion the properties are not the properties of the FRP composite but of the fibers alone. Properties of some commonly available fiber sheet and fabric materials are listed in Table 25.3.

The performance of the FRP strengthening system is highly influenced by the properties of the adhesive layer in the case of the precured systems and by the properties of the saturating polymeric resin in the case of formed-in-place systems. The interface between the FRP composite and the concrete substrate transfers the loads from the concrete to the FRP composite. In the case of flexural and shear (or axial tensile) strengthening, this load transfer is primarily in shear, and the strength and stiffness of the interface layer between the FRP composite and the concrete are critical. Such applications are termed *bond critical*. In the case of axial compressive strengthening or lateral displacement ductility enhancement of columns, the role of the strengthening system is to confine the lateral expansion of the cracked concrete. In this case, the interface bond is not as critical as long as the FRP system is in close contact with the concrete and is wrapped around the concrete continuously so as to provide a confining pressure with appropriate hoop stiffness and strength. Such applications are termed *contact critical*.

The FRP strengthening systems described above all depend on curing of the polymer adhesives or the saturating resins at ambient temperature in the field; therefore, the glass transition temperature (T_g) of these systems is typically quite low (120 to 180°F). The stiffness of the FRP strengthening system is decreased

when the operating temperature approaches (and exceeds) the glass transition temperature. Designers should always be aware of the glass transition temperature of the FRP composite or adhesive they are using in a design. In the event of a fire (at temperatures higher than the T_g in the range of 750°F), the FRP material will decompose (pyrolyze), and its strength and stiffness may be severely compromised in a short time.

25.3.3 Design Basis for FRP Strengthening Systems for Concrete Members

The *load and resistance factor design* (LRFD) basis is stipulated by ACI 440.2R-02 (ACI Committee 440, 2002). Currently, resistance factors are not probabilistically based, and the load factors stipulated for use with this guide are those recommended by ACI 318-99 (e.g., 1.4 for dead loads and 1.7 for live loads) (ACI Committee 318, 1999). (The revised version of the guide, due out in 2008, will have probabilistically based resistance factors and will be compatible with ACI 318-05.) For the design of concrete members with FRP strengthening systems the ACI recommends the following resistance factors (ϕ) and FRP material reduction factors, (ψ_f):

For flexural capacity:

$\phi = 0.9$ for ductile failure of the member following steel yielding ($\epsilon_s > 0.005$).

$\phi = 0.7$ for a brittle failure when the member fails prior to steel yielding ($\epsilon_s < \epsilon_{sy}$).

$\phi = 0.7$ to 0.9 for an intermediate region ($\epsilon_{sy} < \epsilon_s < 0.005$).

$\psi_f = 0.85$ for FRP bond-critical strengths (applied in addition to ϕ factors).

For shear capacity:

$\phi = 0.85$, per ACI 318-99.

$\psi_f = 0.85$ for FRP bond-critical strengths (applied in addition to ϕ factor).

$\psi_f = 0.95$ for FRP contact-critical strengths (applied in addition to ϕ factor).

For axial capacity:

$\phi = 0.75$, per ACI 318-99, for spiral steel column reinforcement.

$\phi = 0.70$, per ACI 318-99, for tied steel column reinforcement.

$\psi_f = 0.95$ for FRP contact-critical strengths (in addition to ϕ factors).

Guaranteed strengths and strains to failure of FRP composite materials for strengthening are defined as the mean minus 3 standard deviations of a minimum of 20 test samples tested in accordance with ACI 440.3R-04 (ACI Committee 440, 2004a). The design strength (f_{fu}) and design failure strain (ϵ_{fu}) are

obtained from the manufacturer-reported guaranteed strength and failure strain by multiplying them by an *environmental reduction factor* (C_E), which depends on the fiber type in the FRP strengthening system and the type of intended service of the structure. For example, for weather-exposed concrete with a glass-reinforced epoxy FRP strengthening system, C_E is 0.65 (ACI Committee 440, 2002). Note that the environmental reduction factors for FRP strengthening systems are not the same as the environmental reduction factors for FRP reinforcing bars (even though the same symbol is used for both.)

Even though flexural strength increases of over 100% of the original strength of a concrete member can be obtained using FRP strengthening systems, the ACI limits the amount of strengthening to prevent catastrophic failure of the concrete member in the event of loss of, or damage to, the strengthening system (due to vandalism or environmental degradation). The ACI recommends that the strengthened member still have sufficient original factored capacity (i.e., discounting the additional strengthening system) to resist a substantial portion of the increased (new) factored load for which the strengthened member is designed. This limit is given as:

$$1.2D + 0.85L \quad (25.28)$$

where D represents the new dead load effect, and L the new live load effect, such as bending moment, shear force, or axial load or their products (stress and strain). To account for environments where the FRP may be exposed to fire, additional restrictions are placed on the factored capacity of the FRP-strengthened structure:

$$1.0D + 1.0L \quad (25.29)$$

Fire protection systems are available to protect FRP strengthening systems to increase their fire ratings to building code required ratings (such as 1- or 2-hour ratings). When a concrete member is strengthened to increase its capacity in a selected mode (e.g., flexure), the member must be checked to ensure that the capacities in other failure modes (e.g., shear) are not exceeded. If this is the case, the strengthening should be decreased or the secondary capacity must be enhanced with its own strengthening system.

For serviceability design, the ACI 440.2R-02 guide limits the stress in the steel at service loads to 80% of the steel yield stress and limits the sustained plus cyclic stress in the FRP strengthening system to account for creep rupture and fatigue, depending on the fiber system. For carbon FRP strengthening systems, this limit is 55% of the ultimate strength. At this time, ACI 440.2R-02 does not provide special recommendations for the determination of deflections or crack widths for FRP-strengthened members. Flexural deflections in the service range can be estimated by use of an effective second moment of area (I_e) analysis, where the tensile contribution of the FRP is added to the contribution of the steel reinforcing. For deflections in flexural members where stresses are in the service load range, the contribution of the FRP strengthening system is typically small. In the inelastic range (after the primary reinforcing steel has yielded), the contribution of the FRP strengthening to the post-yield stiffness can be quite considerable and should be accounted for in inelastic analysis (Bank, 2006).

It is extremely important to note that the method of determining the tensile force resultant in an FRP strengthening system depends on the type of system used. In the bonded, precured strip, the ultimate force is obtained from the strength of the FRP composite (see Table 25.2) and the gross cross-sectional area of the strip. In formed-in-place systems, the ultimate force is obtained from the strength of the fibers and the net area of the fibers (see Table 25.3). The designer must know if the reported strength (and stiffness) of an FRP strengthening system is for the FRP composite (gross composite cross-section) or for the fibers alone (net fiber cross-section). Both methods of calculation are permitted by ACI 440.2R-02.

25.3.4 Design of FRP Flexural Strengthening Systems

Flexural strengthening is achieved by attaching an FRP strengthening system (precured strip or formed-in-place fabric) to the underside of a flexural member to increase the effective tensile force resultant in the member and thereby increase the moment capacity of the member. This is analogous to adding steel strengthening strips (or plates) to the underside of a member; however, two fundamental differences

exist. First, the FRP strengthening system behaves in a linear elastic fashion and does not yield, and, second, the FRP strengthening system is more susceptible to detachment (debonding or delamination) failures than steel plate systems that are anchored with steel bolts in addition to the epoxy bonding. Because the steel plates themselves will yield at a similar strain to the internal steel reinforcing, the stress level in the steel strengthening system is limited. In the case of FRP strengthening with FRP systems having ultimate tensile strengths exceeding 300 ksi (see Table 25.2 and Table 25.3), the stress level in the FRP can be significantly higher than that in steel strengthening systems. In the event that the internal steel reinforcing yields before the FRP strengthening system fails (the desired failure mode), the concrete member will undergo large deflections and cracking. All of these factors lead to the greater likelihood that the FRP strengthening system will debond from the concrete before it achieves its ultimate (longitudinal) tensile strength.

Strengthening of members in flexure can only be achieved if there is sufficient additional compressive capacity in the concrete to allow for the increase in internal moment; therefore, flexural strengthening is most suitable for concrete members that are lightly to moderately reinforced, having steel reinforcement in the range of 20 to 40% of the balanced ratio. This is not uncommon in reinforced concrete members. The existing tensile strain in the concrete at the location of the applied FRP strengthening system due to sustained loads when the FRP strengthening system is applied should be accounted for in design calculations if a shoring system is not used.

The key to flexural strengthening with FRP strengthening systems is to understand the failure modes of the system. These include rupture of the FRP strengthening system, debonding of the FRP strengthening system, or compressive failure of the concrete. All of these modes can occur either before or after the internal steel has yielded. The desired mode of failure is concrete compressive failure after the internal steel has yielded with the FRP strengthening system still attached. The FRP strengthening system can debond in a number of modes. The FRP system can delaminate from the concrete substrate (due to failure in the concrete, the adhesive layer, or in the FRP laminate itself) either at the ends (due to high peeling and shear stresses) or in the interior of the beam due to flexural and shear cracks in the beam at large deflections. For a detailed discussion on debonding failure modes, see Teng et al (2001). Analytical methods to predict the various debonding failure modes are still not fully developed, and ACI 440.2R-02 limits the tensile strain level in the FRP strengthening system to prevent debonding failure by use of an empirically obtained, bond-dependent coefficient (κ_m) that is a function of the unit stiffness of the FRP system and is defined as:

$$\kappa_m = \begin{cases} \frac{1}{60\epsilon_{fu}} \left(1 - \frac{nE_f t_f}{2,000,000} \right) \leq 0.90 & \text{for } nE_f t_f \leq 1,000,000 \text{ lb/in.} \\ \frac{1}{60\epsilon_{fu}} \left(1 - \frac{500,000}{nE_f t_f} \right) \leq 0.90 & \text{for } nE_f t_f > 1,000,000 \text{ lb/in.} \end{cases} \quad (25.30)$$

where ϵ_{fu} is the ultimate strain the FRP; n is the number of layers of FRP strips, sheets, or fabrics; E_f is the longitudinal tensile modulus of the FRP composite in the case of strips or the longitudinal modulus of the fibers in the strengthening direction in the case of sheets or fabrics; and t_f is the thickness of an individual strip in the case of FRP strips or the net thickness of the fibers in a single sheet or fabric in the case of sheets or fabrics.

The strain level in the FRP strengthening system is limited by the strain in the concrete or the ultimate strain in the FRP system and is given as:

$$\epsilon_{fe} = \epsilon_{cu} \left(\frac{h-c}{c} \right) - \epsilon_{bi} \leq \kappa_m \epsilon_{fu} \quad (25.31)$$

where ϵ_{fe} is the effective ultimate strain in the FRP at failure, ϵ_{cu} is the ultimate compressive strain in the concrete (0.003), c is the depth of the neutral axis, h is the depth of the section, and ϵ_{bi} is the existing tensile strain in the concrete substrate at the location of the FRP strengthening system when the FRP system is applied.

The effective stress (f_{fe}) in the FRP is the ultimate strength of the FRP that can be achieved at failure and is linearly related to the ultimate strain as:

$$f_{fe} = E_f \epsilon_{fe} \quad (25.32)$$

The nominal moment capacity (M_n) of the strengthened section (with an existing layer of tensile steel reinforcement) is given as:

$$M_n = A_s f_s \left(d - \frac{\beta_1 c}{2} \right) + \psi_f A_f f_{fe} \left(h - \frac{\beta_1 c}{2} \right) \quad (25.33)$$

with:

$$c = \frac{A_s f_s + A_f f_{fe}}{\gamma'_c \beta_1 b} \quad (25.34)$$

and:

$$f_s = E_s \epsilon_s = E_s \left(\epsilon_{fe} + \epsilon_{bi} \right) \left(\frac{d-c}{h-c} \right) \leq f_y \quad (25.35)$$

where A_s is the area of the tensile steel, f_s is the stress in the steel at failure, d is the depth of the steel reinforcing, β_1 is the depth ratio of the equivalent Whitney stress block, A_f is the area of the FRP strip or the fibers only in a formed-in-place system, γ is the concrete stress resultant factor (0.85 when concrete compressive failure governs), b is the width of the section, and f_y is the yield stress in the reinforcing steel.

The solution to the above equations is typically found by a *trial-and-error* method by assuming a number of layers of a specific strengthening system and calculating the resulting nominal moment. Alternatively, a failure mode can be assumed *a priori* and the stresses in the materials checked using closed-form equations, as described in Bank (2006). According to ACI 440.2R-02, the four currently admissible failure modes are FRP debonding either before or after the internal steel yields or concrete compressive crushing either before or after the internal steel yields. The stress distribution in the concrete at failure of the strengthened member will depend on the failure mode of the strengthened member. If the FRP debonds when the concrete strain is still low (less than 0.002), the failure is controlled by the FRP, and a nonlinear stress distribution in the concrete should be used in determining the compressive force in the section (Bank, 2006). This is not conducive to design calculations, however, and it is typically assumed that the concrete stress can be represented by the Whitney stress block at failure even in this case. Figure 25.4 shows the strains, stresses, and forces in an FRP-strengthened section at the ultimate state according to this assumption. This assumption is felt to be reasonable because in an appropriately designed strengthening system the steel will yield before the FRP debonds or ruptures and the strain in the concrete will be larger than 0.002.

As with a conventional reinforced concrete section, a balanced reinforcement ratio can be defined that includes the effect of the internal steel reinforcing and the externally applied FRP system (Bank, 2006). The balanced ratio can be defined for failure of the section either prior to the internal steel yielding or after the internal steel has yielded, although as mentioned previously the latter is preferable. The balanced reinforcement ratio can be a useful tool in design but is not as important a parameter as in the design of conventional reinforced concrete design (either steel or FRP reinforcement), because a strengthening design depends on the properties of an existing section and it may not be always possible to achieve a balanced condition in the strengthened section. The stresses in the steel and the FRP strengthening system

FIGURE 25.4 Strains, stresses, and forces in an FRP-strengthened section at ultimate loads.

at service loads should be determined using an elastic cracked section and checked against appropriate stress limits for sustained loads on FRP strengthened structures according to ACI 440.2R-02. Mechanical anchorages or FRP wraps can be used to enhance the attachment of the FRP strengthening system to the concrete beam, especially at the ends of the FRP strengthening system. Design guidance is not provided by the ACI 440.2R-02 for this, although the use of such a system is recommended by many manufacturers to prevent debonding failures.

25.3.5 Design of FRP Shear Strengthening Systems

Fiber-reinforced polymer strengthening systems can be used to increase the shear capacity of concrete beams and columns. FRP strengthening systems are applied to the webs of beams (or columns) and function in an analogous fashion to internal steel shear reinforcement. Because FRP shear strengthening systems are applied to concrete members that are often constructed monolithically with other continuous members (such as floors and walls) it is not always possible wrap the FRP strengthening system completely around the member (which is the desirable condition.) The FRP strengthening system must therefore be terminated at the top of the web (a *three-sided U-wrap*) or terminated at both the top and the bottom on the web (a *two-sided wrap*). The non-fully wrapped systems are susceptible to debonding failures (similar to flexural strengthening), and their strains are limited by a shear bond-reduction coefficient (κ_v), which is a function of the concrete strength, the wrapping type used, and the stiffness of the FRP strengthening system. It is given by ACI 440.2R-02 (in U.S. units) as:

$$\kappa_v = \frac{k_1 k_2 L_e}{468 \epsilon_{fu}} \leq 0.75 \quad (25.36)$$

where L_e is the active bond length over which the shear stress is transferred between the FRP and the concrete. It has been shown that it is this finite length that limits the maximum force that can be transferred between the two materials regardless of the bonded length of the FRP strip. It is given as:

$$L_e = \frac{2500}{(n t_f E_f)^{0.58}} \quad (25.37)$$

The coefficients k_1 and k_2 are given as:

$$k_1 = \left(\frac{f'_c}{4000} \right)^{2/3} \quad (25.38)$$

For three-sided shear strengthening systems:

$$k_2 = \frac{d_f - L_e}{d_f} \quad (25.39)$$

For two-sided shear strengthening systems:

$$k_2 = \frac{d_f - 2L_e}{d_f} \quad (25.40)$$

where d_f is the effective depth of the FRP shear strengthening system. For fully wrapped sections, it is equal to the full depth (h) of the section, but for two- and three-sided wraps it is the vertical distance from the top of the FRP system to the main tensile reinforcing bars in the beam and is less than h .

The nominal shear capacity of an FRP strengthened concrete member with existing steel shear reinforcing is determined by adding the contribution of the FRP strengthening system to the existing shear capacity and is given as:

$$V_n = V_c + V_s + \psi_f V_f \quad (25.41)$$

where:

$$V_f = \frac{A_{fv} f_{fe} (\sin \alpha + \cos \alpha) d_f}{s_f} \quad (25.42)$$

$$A_{fv} = 2nt_f w_f \quad (25.43)$$

$$f_{fe} = E_f \epsilon_{fe} \quad (25.44)$$

where V_c is the shear capacity of the concrete, V_s is the shear capacity of the existing steel shear reinforcement, and V_f is the shear capacity of the FRP strengthening system. The FRP material reduction factor (ψ_f) is taken as 0.95 for completely wrapped *contact-critical* sections and as 0.85 for *bond-critical* two- or three-sided wrapped sections. A_{fv} is the area of the FRP shear strengthening system, f_{fe} is the effective tensile stress in the FRP at ultimate, α is the inclination of the fiber in the FRP strengthening system to the longitudinal axis of the member, s_f is the center-to-center spacing of the FRP shear strengthening strips, and w_f is the width of the FRP shear strengthening strip. (For a continuous FRP shear strengthening sheet or fabric, $s_f = w_f$). E_f is the longitudinal modulus of the FRP strengthening system, and ϵ_{fe} is the effective longitudinal strain in the FRP strengthening system.

The effective strain in the FRP shear strengthening system is limited to prevent debonding failures and to maintain the integrity of the concrete aggregate interlock in the concrete member. For completely wrapped FRP shear strengthening systems, the maximum effective strain in the FRP strengthening system at failure is limited to:

$$\epsilon_{fe} = 0.004 \leq 0.75 \epsilon_{fu} \quad (25.45)$$

For two- or three-sided shear strengthening, the effective shear strain in the FRP strengthening system at failure is limited to:

$$\epsilon_{fe} = \kappa_v \epsilon_{fu} \leq 0.004 \quad (25.46)$$

Mechanical anchorages can be used to anchor two- or three-sided wraps in the compression zone of the web; however, design guidance is not provided by ACI 440.2R-02.

When FRP shear strengthening is added to the conventional steel shear reinforcement, the shear reinforcement limit for conventional concrete members must hold for both types of reinforcement:

$$V_s + V_f \leq 8\sqrt{f'_c}b_wd \quad (25.47)$$

When intermittent strips are used, a maximum spacing between the strips is mandated so every shear crack will be covered by sufficient strip width. The following maximum spacing of intermittent strips is required:

$$s_f^{\max} = \frac{d_f}{4} + w_f \quad (25.48)$$

25.3.6 Design of FRP Axial Strengthening Systems

Concrete compression members can be strengthened to increase their axial load carrying capacity, their shear capacity, their steel rebar lap splice capacity, and their lateral load carrying deformation capacity (which is related to the ductility of the member). FRP strengthening of columns is most effective when applied to circular columns and must always consist of complete wrapping to obtain confinement of the concrete. FRP strengthening systems for confinement of columns are classified as *contact-critical* applications. It is also important to note that FRP axial strengthening systems are regarded as *passive* systems; that is, they are not effective (or active) until the concrete reaches its transverse cracking strain and begins to dilate, thus placing hoop stress on the FRP wrap. This is in contrast to the FRP flexural and shear strengthening systems that must be active at all load levels.

For a non-slender, non-prestressed, normal weight concrete column reinforced with steel *spiral reinforcement*, the nominal axial capacity is given as:

$$P_n = 0.85 \left(0.85 \psi_f f'_{cc} (A_g - A_{st}) + f_y A_{st} \right) \quad (25.49)$$

and for steel *tied reinforcement*, the nominal axial capacity is given as:

$$P_n = 0.80 \left(0.85 \psi_f f'_{cc} (A_g - A_{st}) + f_y A_{st} \right) \quad (25.50)$$

The confined compressive strength (f'_{cc}) is given in ACI 440.2R-02 as:

$$f'_{cc} = f'_c \left(2.25 \sqrt{1 + 7.9 \frac{f_l}{f'_c}} - 2 \frac{f_l}{f'_c} - 1.25 \right) \quad (25.51)$$

where f_l is the confining pressure provided by the FRP wrap and is given as:

$$f_l = \frac{\kappa_a \rho_f E_f \epsilon_{fe}}{2} \quad (25.52)$$

where A_g is the gross area of the concrete; A_{st} is the area of the existing longitudinal steel; f_y is the yield stress in the steel bars; f'_c is the unconfined (existing) concrete compressive strength; ψ_f is the FRP material reduction factor taken as 0.95 for this contact-critical application; κ_a is an efficiency factor that depends on the shape of the column; ρ_f is the reinforcement ratio of the FRP system; E_f is the modulus of the FRP system in the hoop direction; and ϵ_{fe} is the effective strain the FRP system in the hoop direction.

For circular columns, κ_a is 1.0 and the reinforcement ratio is given as:

$$\rho_f = \frac{A_f}{A_g} = \frac{4nt_f}{h} \quad (25.53)$$

where h is the diameter of the circular column. It is important to note that the fiber layers must all be oriented in the hoop direction around the column (or, if they are not, the effective properties of the FRP system in the hoop direction must be used). If layers are also oriented in the longitudinal direction (e.g., for flexural strengthening), these layers should not be considered to contribute to the axial strengthening. For noncircular columns, FRP strengthening to increase axial capacity is much less effective due to stress concentrations at the corners (even when chamfered) and the nonuniform confining pressure developed by the wrap. See Teng et al. (2001) for more discussion and proposed equations to address this topic.

Limits are placed on the amount of FRP axial strengthening to ensure that the concrete does not approach its transverse cracking strain nor the steel its yield strain in the service range. ACI 440.2R-02 limits the service load stress in the concrete to $0.65f'_c$ and the service load stress in the longitudinal steel to $0.60f_y$. The stresses in the concrete ($f_{c,s}$) and the steel ($f_{s,s}$) at service loads are found using traditional mechanics of materials formulae:

$$f_{c,s} = p_s \left(\frac{E_c}{A_c E_c + A_{st} E_s} \right) \quad (25.54)$$

and

$$f_{s,s} = p_s \left(\frac{E_s}{A_c E_c + A_{st} E_s} \right) \quad (25.55)$$

where p_s is the axial load at service conditions in the FRP-strengthened column.

25.3.6.1 Ductility Enhancement

The lateral displacement capacity, which is related to the ductility of a concrete column, can also be increased by confining it with FRP strengthening wraps. The determination of the lateral displacement capacity is beyond the scope of ACI 440.2R-02 and is addressed in a number of texts related to the seismic capacity of concrete structures (Paulay and Priestley, 1992; Priestley et al., 1996). One of the key parameters used in determining the lateral displacement capacity of a concrete column is the maximum confined concrete compressive strain (ϵ'_{cc}), which is the failure strain in the concrete in the large-deformation, inelastic range. The maximum concrete compressive strain is typically greater than ϵ_{cu} , which is the assumed nominal concrete strain at failure (based on standard unreinforced cylinder tests), and is stipulated by the ACI as 0.003. This is due to the fact that the concrete in the compression zone in a member is confined by the transverse reinforcing steel (stirrups, ties, hoops or spirals). By using an FRP wrap on the exterior of the member, the concrete in the compression zone can be confined in a similar manner and the maximum concrete strain at ultimate can be increased to a confined compressive strain (ϵ'_{cc}). The equation provided by ACI 440.2R-02 for the maximum confined concrete compressive strain of an FRP wrapped column is:

$$\epsilon'_{cc} = \frac{1.71(5f'_{cc} - 4f'_c)}{E_c} \quad (25.56)$$

where E_c is the elastic modulus of the concrete and f'_{cc} is as defined previously. This equation is valid for both circular and rectangular columns. To use the equation for rectangular columns, the efficiency factor (κ_a) is calculated from:

$$\kappa_a = 1 - \frac{(b - 2r)^2 + (h - 2r)^2}{3bh(1 - \rho_g)} \quad (25.57)$$

where h and b are the depth and breadth of the rectangular concrete column, r is the corner radius, and $\rho_g = A_{st}/A_g$ is the steel reinforcement ratio. This equation is only applicable when $h/b \leq 1.5$ and when

both b and h are less than 36 in., as it has been shown that ductility enhancement in rectangular columns with larger aspect ratios and longer sides is negligible. The FRP reinforcement ratio for a rectangular FRP confined column is given as:

$$\rho_f = \frac{2nt_f(b+h)}{bh} \quad (25.58)$$

It is important to recognize that, even though a confined compressive strength for a rectangular column is calculated as an intermediate step to calculating the confined compressive strain, this confined strength should not be used to determine any strength increase in the column.

25.4 Summary

The fundamental considerations and the basic equations that are used to design FRP-reinforced and FRP-strengthened concrete members have been presented in this chapter. The design procedures presented are those promulgated in design guides published by the American Concrete Institute, but it is important to note that these guides are often updated as new research is conducted in this rapidly evolving area of concrete structures. Readers are therefore advised to make sure to obtain the current versions of these guides when designing FRP-reinforced and FRP-strengthened concrete members. Even though the equations and the factors may change in forthcoming versions of these guides, the fundamental concepts presented in this chapter will remain the basis for the design procedures provided. At this time, the properties of the FRP materials for use with the equations presented in this chapter and with the ACI guides must be obtained from the manufacturers of the FRP products being used. Efforts are underway at a number of organizations to develop standard specifications for FRP-reinforcing and FRP-strengthening materials for use in concrete structures.

26.1 Introduction

Portland cement concrete is one of the most widely used construction materials. As the demand for concrete as a construction material increases, so, too, does the demand for Portland cement. It is estimated that the production of cement will increase from about 1.5 billion tons in 1995 to 2.2 billion tons by 2010 (Malhotra, 1999). On the other hand, climate changes due to global warming have become a major concern. Global warming is caused by the emission of greenhouse gases, such as carbon dioxide (CO_2), into the atmosphere by human activities. Among the greenhouse gases, CO_2 contributes about 65% of global warming (McCaffrey, 2002). The cement industry is held responsible for some of the CO_2 emissions, because the production of 1 ton of Portland cement emits approximately 1 ton of CO_2 into

* Emeritus Professor of Civil Engineering and Past Dean, Faculty of Engineering, Curtin University of Technology, Perth, Australia; expert in concrete structural systems and high-strength materials technology.

the atmosphere (Davidovits, 1994; McCaffrey, 2002). Several efforts are in progress to reduce the use of Portland cement in concrete to address the global warming issues. These include the utilization of supplementary cementing materials such as fly ash, silica fume, granulated blast-furnace slag, rice-husk ash, and metakaolin, as well as the development of alternative binders to Portland cement. In this respect, the geopolymer technology proposed by Davidovits (1988) shows considerable promise for application in the concrete industry as an alternative binder to Portland cement. In terms of reducing global warming, the geopolymer technology could reduce CO₂ emissions to the atmosphere caused by the cement and aggregates industries by about 80% (Davidovits, 1994).

26.2 Geopolymers

Davidovits (1988, 1994) proposed that an alkaline liquid could be used to react with the silicon (Si) and the aluminum (Al) in a source material of geological origin or in by-product materials such as fly ash and rice-husk ash to produce binders. Because the chemical reaction that takes place in this case is a polymerization process, he coined the term *geopolymer* to represent these binders. Geopolymers are members of the family of inorganic polymers. The chemical composition of the geopolymer material is similar to natural zeolitic materials, but the microstructure is amorphous. The polymerization process involves a substantially fast chemical reaction under alkaline conditions on silicon–aluminum minerals that results in a three-dimensional polymeric chain and ring structure consisting of Si–O–Al–O bonds (Davidovits, 1994). To date, the exact mechanism of setting and hardening of the geopolymer material is not clear, but the formation of geopolymer materials can be described as shown in Equation 26.1 and Equation 26.2 (Davidovits, 1994; van Jaarsveld et al., 1997):

The last term in Equation 26.2 reveals that water is released during the chemical reaction that occurs during the formation of geopolymers. This water, expelled from the geopolymer matrix during the curing and further drying periods, leaves behind discontinuous nanopores in the matrix which provide benefits to the performance of geopolymers. The water in a geopolymer mixture, therefore, plays no role in the chemical reaction that takes place; it merely provides workability to the mixture during handling. This is in contrast to the chemical reaction of water in a Portland cement concrete mixture during the hydration process.

The two main constituents of geopolymers are the source materials and the alkaline liquids. The source materials for geopolymers based on alumina–silicate should be rich in silicon (Si) and aluminum (Al). These could be natural minerals such as kaolinite, clays, etc. Alternatively, by-product materials such as fly ash, silica fume, slag, rice-husk ash, red mud, etc. could be used as source materials. The choice of the source materials for making geopolymers depends on factors such as availability, cost, type of application, and specific demands of the end users. The alkaline liquids are obtained from soluble alkali metals that are usually sodium or potassium based. The most common alkaline liquid used in geopolymerization is a combination of sodium hydroxide (NaOH) or potassium hydroxide (KOH) and sodium silicate or potassium silicate.

This chapter is devoted to heat-cured, low-calcium, fly-ash-based geopolymer concrete. Low-calcium (ASTM Class F) fly ash is preferred as a source material over high-calcium (ASTM Class C) fly ash. The presence of calcium in high amounts may interfere with the polymerization process and alter the micro-structure (Gourley, 2003; Gourley and Johnson, 2005).

26.3 Constituents of Geopolymer Concrete

Geopolymer concrete can be manufactured by using the low-calcium (ASTM Class F) fly ash obtained from coal-burning power stations. The chemical composition and the particle size distribution of the fly ash must be established prior to use. An x-ray fluorescence (XRF) analysis may be used to determine the chemical composition of the fly ash. Low-calcium fly ash has been used successfully to manufacture geopolymer concrete for which the silicon and aluminum oxides constituted about 80% by mass, with a Si/Al ratio of about 2. The content of the iron oxide usually ranged from 10 to 20% by mass, whereas the calcium oxide content was less than 3% by mass. The carbon content of the fly ash, as indicated by the loss on ignition by mass, was as low as <2%. The particle size distribution tests revealed that 80% of the fly ash particles were smaller than 50 μm (Gourley, 2003; Hardjito and Rangan, 2005). Coarse and fine aggregates used by the concrete industry are suitable for the manufacture of geopolymer concrete. The grading curves currently used in concrete practice are applicable in the case of geopolymer concrete (Gourley, 2003; Hardjito and Rangan, 2005).

A combination of sodium silicate solution and sodium hydroxide (NaOH) solution can be used as the alkaline liquid. It is recommended that the alkaline liquid be prepared by mixing both of the solutions together at least one day prior to use. The sodium silicate solution is commercially available in various grades. A solution with a $\text{Na}_2\text{O}/\text{SiO}_2$ ratio by mass of approximately 2 (say, $\text{Na}_2\text{O} = 14.7\%$, $\text{SiO}_2 = 29.4\%$, and water = 55.9%) is recommended. Sodium hydroxide with 98% purity, in flake or pellet form, is commercially available. The solids must be dissolved in water to make a solution with the required concentration. The concentration of sodium hydroxide solution can vary in from 8 to 16 molar. The mass of NaOH solids in a solution varies depending on the concentration of the solution; for example, NaOH solution with a concentration of 8 molar consists of $8 \times 40 = 320$ g of NaOH solids per liter of the solution, where 40 is the molecular weight of NaOH. The mass of NaOH solids has been measured as 262 g per kg of NaOH solution with a concentration of 8 molar. Similarly, the mass of NaOH solids per kg of the solution for other concentrations has been measured as 10 molar for 314 g, 12 molar for 361 g, 14 molar for 404 g, and 16 molar for 444 g (Hardjito and Rangan, 2005). Note that the mass of NaOH solids is only a fraction of the mass of the NaOH solution, and water is the major component. To improve the workability, a high-range, water-reducer (HRWR) superplasticizer and extra water may be added to the mixture.

26.4 Mixture Proportions of Geopolymer Concrete

The primary difference between geopolymer concrete and Portland cement concrete is the binder. The silicon and aluminum oxides in the low-calcium fly ash react with the alkaline liquid to form the geopolymer paste that binds the loose coarse aggregates, fine aggregates, and other unreacted materials together to form the geopolymer concrete. As in the case of Portland cement concrete, the coarse and fine aggregates occupy about 75 to 80% of the mass of geopolymer concrete. This component of geopolymer concrete mixtures can be designed using the tools currently available for Portland cement concrete. The compressive strength and workability of geopolymer concrete are influenced by the proportions and properties of the constituent materials that make the geopolymer paste. Experimental results (Hardjito and Rangan, 2005) have shown the following:

- A higher concentration (in terms of molar) of the sodium hydroxide solution results in higher compressive strength of geopolymer concrete.
- The higher the ratio of sodium silicate solution to sodium hydroxide solution by mass, the higher the compressive strength of geopolymer concrete.

FIGURE 26.1 Effect of water-to-geopolymer solids ratio by mass on compressive strength of geopolymer concrete. (From Hardjito, D. and Rangan, B.V., *Development and Properties of Low-Calcium Fly-Ash-Based Geopolymer Concrete*, Research Report GC1, Faculty of Engineering, Curtin University of Technology, Perth, 2005.)

- The addition of naphthalene-sulfonate-based superplasticizer, up to approximately 4% of fly ash by mass, improves the workability of the fresh geopolymer concrete; however, there is a slight degradation in the compressive strength of hardened concrete when the superplasticizer dosage is greater than 2%.
- The slump value of the fresh geopolymer concrete increases when the water content of the mixture increases.
- As the $\text{H}_2\text{O}/\text{Na}_2\text{O}$ molar ratio increases, the compressive strength of geopolymer concrete decreases.
- The effect of the $\text{Na}_2\text{O}/\text{Si}_2\text{O}$ molar ratio on the compressive strength of geopolymer concrete is not significant.

As can be seen from the above, the effects of various parameters on the compressive strength and workability of geopolymer concrete are complex. To assist in the design of low-calcium, fly-ash-based geopolymer concrete mixtures, a single parameter called the **water/geopolymer solids ratio** by mass was devised. In this parameter, the total mass of water is the sum of the mass of water contained in the sodium silicate solution, the mass of water in the sodium hydroxide solution, and the mass of extra water, if any, added to the mixture. The mass of geopolymer solids is the sum of the mass of fly ash, the mass of sodium hydroxide solids, and the mass of solids in the sodium silicate solution (i.e., the mass of Na_2O and SiO_2).

Tests were performed to establish the effect of the water/geopolymer solids ratio by mass on the compressive strength and workability of geopolymer concrete. The test specimens were 100×200 -mm cylinders, heat cured in an oven at various temperatures for 24 hours. The results of these tests, plotted in Figure 26.1, show that the compressive strength of geopolymer concrete decreases as the water/geopolymer solids ratio by mass increases (Hardjito and Rangan, 2005). This test trend is analogous to the well-known effect of the water/cement ratio on the compressive strength of Portland cement concrete. Obviously, as the water/geopolymer solids ratio increases, workability increases because the mixtures contain more water.

26.5 Mixing, Casting, and Compaction of Geopolymer Concrete

Geopolymer concrete can be manufactured by adopting the conventional techniques used in the manufacture of Portland cement concrete. In the laboratory, the fly ash and the aggregates are first mixed together dry in an 80-L capacity pan mixer for about 3 minutes. The alkaline liquid is mixed with the

FIGURE 26.2 Effect of wet-mixing time on compressive strength of geopolymer concrete. (From Hardjito, D. and Rangan, B.V., *Development and Properties of Low-Calcium Fly-Ash-Based Geopolymer Concrete*, Research Report GC1, Faculty of Engineering, Curtin University of Technology, Perth, 2005.)

superplasticizer and extra water, if any. The liquid component of the mixture is then added to the dry materials, and the mixing continues for another 4 minutes. The fresh concrete can be handled up to 120 minutes without any sign of setting and without any degradation in the compressive strength. The fresh concrete can be cast and compacted by the usual methods for Portland cement concrete (Hardjito and Rangan, 2005; Sumajouw and Rangan, 2006; Wallah and Rangan, 2006). The compressive strength of geopolymer concrete is influenced by the wet-mixing time, as illustrated by the test data plotted in Figure 26.2. The test specimens were 100×200 -mm cylinders, steam-cured at 60°C for 24 hours, and tested in compression at an age of 21 days. Figure 26.2 shows that the compressive strength significantly increased as the wet-mixing time increased. The slump values of fresh concrete were also measured. These results showed that the slump values decreased from 240 mm for 2 minutes of wet-mixing time to 210 mm when the wet-mixing time increased to 16 minutes.

26.6 Curing of Geopolymer Concrete

Although low-calcium, fly-ash-based geopolymer concrete can be cured in ambient conditions, heat curing is generally recommended. Heat curing substantially assists the chemical reaction that occurs in the geopolymer paste. Both curing time and curing temperature influence the compressive strength of geopolymer concrete. The effect of curing time is illustrated in Figure 26.3 (Hardjito and Rangan, 2005). The test specimens were 100×200 -mm cylinders heat cured at 60°C in an oven. The curing time varied from 4 hr to 96 hr (4 days). Longer curing time improved the polymerization process, resulting in higher compressive strength. The rate of increase in strength was rapid up to 24 hr of curing time; beyond 24 hr, the gain in strength was only moderate. Thus, the heat-curing time need not be more than 24 hr in practical applications.

Figure 26.4 shows the effect of curing temperature on the compressive strength of geopolymer concrete (Hardjito and Rangan, 2005). The test specimens were 100×200 -mm cylinders heat cured in an oven for 24 hr. Higher curing temperatures resulted in greater compressive strength, although an increase in the curing temperature beyond 60°C did not increase the compressive strength substantially. The effect of curing temperature on the compressive strength is also indicated by the test data shown in Figure 26.1. Based on these test trends, a curing temperature of about 60°C is recommended.

Heat curing can be achieved by either steam curing or dry curing. Test data show that the compressive strength of dry-cured geopolymer concrete is approximately 15% larger than that of steam-cured geopolymer concrete (Hardjito and Rangan, 2005). The required heat-curing regime can be manipulated to fit the needs of practical applications. In laboratory trials, precast products were manufactured using geopolymer concrete; the design specifications required steam curing at 60°C for 24 hours. To optimize

FIGURE 26.3 Effect of curing time on compressive strength of geopolymer concrete. (From Hardjito, D. and Rangan, B.V., *Development and Properties of Low-Calcium Fly-Ash-Based Geopolymer Concrete*, Research Report GC1, Faculty of Engineering, Curtin University of Technology, Perth, 2005.)

FIGURE 26.4 Effect of curing temperature on compressive strength of geopolymer concrete. (From Hardjito, D. and Rangan, B.V., *Development and Properties of Low-Calcium Fly-Ash-Based Geopolymer Concrete*, Research Report GC1, Faculty of Engineering, Curtin University of Technology, Perth, 2005.)

the usage of formwork, the products were cast and steam cured initially for about 4 hr. The steam curing was then stopped for some time to allow release of the products from the formwork. The steam curing of the products then continued for another 21 hr. This two-stage steam-curing regime did not produce any degradation in the strength of the products. The initiation of heat curing geopolymer concrete can be delayed for several days. Tests have shown that a delay in the start of heat curing up to 5 days did not produce any degradation in the compressive strength. In fact, such a delay in the start of heat curing substantially increased the compressive strength of geopolymer concrete (Hardjito and Rangan, 2005). These flexibilities in the heat-curing regime of geopolymer concrete can be exploited in practical applications.

26.7 Design of Geopolymer Concrete Mixtures

The concrete mixture design process is vast and generally based on performance criteria. Based on the information given in the previous three sections, some simple guidelines for the design of heat-cured, low-calcium, fly-ash-based geopolymer concrete are proposed here. The role and the influence of aggregates are considered to be the same as in the case of Portland cement concrete. The mass of combined aggregates may be taken to be between 75 and 80% of the mass of geopolymer concrete. The performance criteria of a geopolymer concrete mixture depend on the application. For simplicity, the compressive

TABLE 26.1 Data for the Design of Low-Calcium, Fly-Ash-Based Geopolymer Concrete Mixtures

Water/Geopolymer Solids Ratio (by mass)	Workability	Design Compressive Strength (Wet-Mixing Time of 4 Minutes, Steam Curing at 60°C for 24 Hours after Casting)
		(MPa)
0.16	Very stiff	60
0.18	Stiff	50
0.20	Moderate	40
0.22	High	35
0.24	High	30

Note: The fineness modulus of combined aggregates is taken to be in the range of 4.5 to 5.0. When cured in dry heat, the compressive strength may be about 15% larger than the values given above. When the wet-mixing time is increased from 4 minutes to 16 minutes, these compressive strength values may increase by about 30%. The standard deviation of compressive strength is about 10% of the values given above.

strength of hardened concrete and the workability of fresh concrete are selected as the performance criteria. To meet these performance criteria, the alkaline liquid/fly ash ratio by mass, water/geopolymer solids ratio (see Section 26.4 for definition) by mass, the wet-mixing time, the heat-curing temperature, and the heat-curing time are selected as parameters.

With regard to the alkaline liquid/fly ash ratio by mass, values in the range of 0.30 to 0.45 are recommended. Based on results obtained from numerous mixtures made in the laboratory over a period of 4 years, the data given in Table 26.1 are proposed for the design of low-calcium, fly-ash-based geopolymer concrete. Note that a wet-mixing time of 4 minutes and steam curing at 60°C for 24 hr after casting are proposed. The data given in Figure 26.3 and Figure 26.4 may be used as guides to choose other curing temperatures and curing times.

Sodium silicate solution is less expensive than sodium hydroxide solids. Commercially available sodium silicate solution A53 with a $\text{Na}_2\text{O}/\text{SiO}_2$ ratio by mass of approximately 2 (say, $\text{Na}_2\text{O} = 14.7\%$, $\text{SiO}_2 = 29.4\%$, and water = 55.9% by mass) and sodium hydroxide solids (NaOH) with 97 to 98% purity are recommended. Laboratory experience suggests that the ratio of sodium silicate solution to sodium hydroxide solution by mass may be taken as approximately 2.5 (Hardjito and Rangan, 2005).

The mixture design process is illustrated by the following example. A mixture proportion of heat-cured, low-calcium, fly-ash-based geopolymer concrete with a design compressive strength of 45 MPa is required for precast concrete products. Assume that normal-density aggregates are to be used and the unit weight of concrete is 2400 kg/m³. Take the mass of the combined aggregates as 77% of the mass of concrete (i.e., $0.77 \times 2400 = 1848$ kg/m³). The combined aggregates may be selected to match the standard grading curves used in the design of Portland cement concrete mixtures; for example, the aggregates may be comprised of 277 kg/m³ (15%) of 20-mm aggregates, 370 kg/m³ (20%) of 14-mm aggregates, 647 kg/m³ (35%) of 7-mm aggregates, and 554 kg/m³ (30%) of fine sand to meet the requirements of standard grading curves. The fineness modulus of the combined aggregates is approximately 5.0.

The mass of low-calcium fly ash and the alkaline liquid = $2400 - 1848 = 552$ kg/m³. Taking the alkaline liquid/fly ash ratio by mass as 0.35, the mass of fly ash = $552/(1 + 0.35) = 408$ kg/m³ and the mass of alkaline liquid = $552 - 408 = 144$ kg/m³. Taking the ratio of sodium silicate solution to sodium hydroxide solution by mass as 2.5, the mass of sodium hydroxide solution = $144/(1 + 2.5) = 41$ kg/m³ and the mass of the sodium silicate solution = $144 - 41 = 103$ kg/m³. Therefore, the trial mixture proportion is as follows: combined aggregates = 1848 kg/m³, low-calcium fly ash = 408 kg/m³, sodium silicate solution = 103 kg/m³, and sodium hydroxide solution = 41 kg/m³.

To manufacture the geopolymer concrete mixture, commercially available sodium silicate solution A53 with a $\text{Na}_2\text{O}/\text{SiO}_2$ ratio by mass of approximately 2 (say, $\text{Na}_2\text{O} = 14.7\%$, $\text{SiO}_2 = 29.4\%$, and water = 55.9% by mass) is selected. Sodium hydroxide solids (NaOH) with 97 to 98% purity are purchased from commercial sources and mixed with water to make a solution with a concentration of 8 molar. This solution is comprised of 26.2% of NaOH solids and 73.8% water by mass (see Section 26.3).

For the trial mixture, the water/geopolymer solids ratio by mass is calculated as follows. In sodium silicate solution, water = $0.559 \times 103 = 58$ kg and solids = $103 - 58 = 45$ kg. In sodium hydroxide solution, solids = $0.262 \times 41 = 11$ kg and water = $41 - 11 = 30$ kg. Therefore, the total mass of water = $58 + 30 = 88$ kg, and the mass of geopolymer solids = 408 (i.e., mass of fly ash) + $45 + 11 = 464$ kg; hence, the water/geopolymer solids ratio by mass = $88/464 = 0.19$. Using the data given in Table 26.1 for a water/geopolymer solids ratio by mass of 0.19, the design compressive strength is approximately 45 MPa, as required. The geopolymer concrete mixture proportion is therefore as follows:

20-mm aggregates = 277 kg/m^3 .

14-mm aggregates = 370 kg/m^3 .

7-mm aggregates = 647 kg/m^3 .

Fine sand = 554 kg/m^3 .

Low-calcium fly ash (ASTM Class F) = 408 kg/m^3 .

Sodium silicate solution A53 ($\text{Na}_2\text{O} = 14.7\%$, $\text{SiO}_2 = 29.4\%$, and water = 55.9% by mass) = 103 kg/m^3 .

Sodium hydroxide solution (8 molar) = 41 kg/m^3 .

Note that the 8-molar sodium hydroxide solution is made by mixing 11 kg of sodium hydroxide solids with 97 to 98% purity in 30 kg of water. The aggregates are assumed to be in saturated-surface-dry condition. The geopolymer concrete must be wet mixed at least for 4 minutes and steam cured at 60°C for 24 hr after casting. The workability of fresh geopolymer concrete is expected to be moderate. If necessary, a commercially available superplasticizer of about 1.5% of mass of fly ash (i.e., $408 \times 1.5/100 = 6 \text{ kg/m}^3$) may be added to the mixture to facilitate ease of placement of fresh concrete.

Numerous batches of this example geopolymer concrete mixture have been manufactured and tested in the laboratory over a period of 4 years. These test results have shown that the mean 7th-day compressive strength was 56 MPa with a standard deviation of 3 MPa (see Mixture 1 in Table 26.4 and Table 26.5). The mean slump of the fresh geopolymer concrete was about 100 mm. This example is used to illustrate the effects of the alkaline liquid/fly ash ratio by mass on the compressive strength and workability of geopolymer concrete. The example can be reworked using different values of the alkaline liquid/fly ash ratio by mass, and, based on the data given in Table 26.1, the following results are obtained:

Alkaline Liquid/ Fly Ash by Mass	Water/Geopolymer Solids by Mass	Workability	Compressive Strength (MPa)
0.30	0.165	Stiff	58
0.35	0.190	Moderate	45
0.40	0.210	Moderate	37
0.45	0.230	High	32

26.8 Short-Term Properties of Geopolymer Concrete

26.8.1 Behavior in Compression

The behavior and failure modes of fly-ash-based geopolymer concrete in compression are similar to those of Portland cement concrete. Figure 26.5 shows a typical stress–strain curve of geopolymer concrete. Test data show that the strain at peak stress is in the range of 0.0024 to 0.0026 (Hardjito and Rangan, 2005). Collins et al. (1993) proposed that the stress–strain relation of Portland cement concrete in compression can be predicted using the following expression:

$$\sigma_c = f_{cm} \frac{\epsilon_c}{\epsilon_{cm}} \frac{n}{n-1 + \left(\epsilon_c / \epsilon_{cm} \right)^{nk}} \quad (26.3)$$

FIGURE 26.5 Stress–strain relation of geopolymer concrete in compression. (From Hardjito, D. and Rangan, B.V., *Development and Properties of Low-Calcium Fly-Ash-Based Geopolymer Concrete*, Research Report GC1, Faculty of Engineering, Curtin University of Technology, Perth, 2005.)

where f_{cm} = peak stress, ϵ_{cm} = strain at peak stress, $n = 0.8 + (f_{cm}/17)$, and $k = 0.67 + (f_{cm}/62)$ when $\epsilon_c/\epsilon_{cm} > 1$ or equal to 1.0 when $\epsilon_c/\epsilon_{cm} \leq 1$. Figure 26.5 shows that the measured stress–strain curve correlates well with that calculated using Equation 26.3.

Table 26.2 gives the measured values of the modulus of elasticity (E_c) of geopolymer concrete in compression. As expected, the modulus of elasticity increases as the compressive strength of geopolymer concrete increases (Hardjito and Rangan, 2005). For Portland cement concrete, the draft Australian Standard AS 3600 (Committee BD-002, 2005) recommends the following expression to calculate the value of the modulus of elasticity within an error of $\pm 20\%$:

$$E_c = \rho^{1.5} (0.024\sqrt{f_{cm}} + 0.12) \quad (\text{MPa}) \quad (26.4)$$

where ρ is the unit weight of concrete in kg/m^3 , and f_{cm} is the mean compressive strength in MPa.

The American Concrete Institute (ACI) Committee 363 (1992) recommended the following expression to calculate the modulus of elasticity:

$$E_c = 3320\sqrt{f_{cm}} + 6900 \quad (\text{MPa}) \quad (26.5)$$

The average unit weight of the fly-ash-based geopolymer concrete was 2350 kg/m^3 . Table 26.2 provides a comparison between the measured values of the modulus of elasticity of fly-ash-based geopolymer concrete with the values calculated using Equation 26.4 and Equation 26.5. It can be seen from Table 26.2 that the measured values were consistently lower than the values calculated using Equation 26.4 and Equation 26.5. This is due to the type of coarse aggregates used in the manufacture

TABLE 26.2 Modulus of Elasticity of Geopolymer Concrete in Compression

f_{cm}	E_c (Measured) (GPa)	E_c (Equation 26.4) (GPa)	E_c (Equation 26.5) (GPa)
89	30.8	39.5 ± 7.9	38.2
68	27.3	36.2 ± 7.2	34.3
55	26.1	33.9 ± 6.8	31.5
44	23.0	31.8 ± 6.4	28.9

TABLE 26.3 Indirect Tensile Splitting Strength of Geopolymer Concrete

Mean Compressive Strength (MPa)	Mean Indirect Tensile Strength (MPa)	Characteristic Principal Tensile Strength (Equation 26.6) (MPa)	Splitting Strength (Equation 26.7) (MPa)
89	7.43	3.77	5.98

55	5.45	3.00	4.34
44	4.43	2.65	3.74

of geopolymer concrete. The type of the coarse aggregate used in the test program was of a granite type. Even in the case of specimens made of mixture with $f_{cm} = 44$ MPa, the failure surface of test cylinders cut across the coarse aggregates, thus resulting in a smooth failure surface. This indicates that the coarse aggregates were weaker than the geopolymer matrix and the matrix–aggregate interface (Hardjito and Rangan, 2005). For Portland cement concrete using a granite-type coarse aggregate, Aitcin and Mehta (1990) reported modulus of elasticity values of 31.7 and 33.8 GPa when f_{cm} was equal to 84.8 and 88.6 MPa, respectively. These values are similar to those measured for geopolymer concrete given in Table 26.2. The Poisson's ratio of fly-ash-based geopolymer concrete with compressive strength in the range of 40 to 90 MPa falls between 0.12 and 0.16. These values are similar to those of Portland cement concrete.

26.8.2 Indirect Tensile Strength

The tensile strength of fly-ash-based geopolymer concrete was measured by performing the cylinder splitting test on 150 × 300-mm concrete cylinders (Hardjito and Rangan, 2005). The test results are given in Table 26.3. These test results show that the tensile splitting strength of geopolymer concrete is only a fraction of the compressive strength, as in the case of Portland cement concrete. The draft Australian Standards for Concrete Structures AS 3600 (Committee BD-002, 2005) recommends the following design expression to determine the characteristic principal tensile strength (f_{ct}) of Portland cement concrete:

$$f_{ct} = 0.4\sqrt{f_{cm}} \quad (\text{MPa}) \quad (26.6)$$

Neville (2000) suggested that the relation between the tensile splitting strength and the compressive strength of Portland cement concrete may be expressed as:

$$f_{ct} = 0.3(f_{cm})^{2/3} \quad (\text{MPa}) \quad (26.7)$$

The calculated values of f_{ct} using Equation 26.6 and Equation 26.7 are also given in Table 26.3, which shows that the indirect tensile strength of fly-ash-based geopolymer concrete is larger than the values recommended by the draft Australian Standard AS 3600 (Committee BD-002, 2005) and Neville (2000) for Portland cement concrete.

26.8.3 Unit Weight

The unit weight of concrete primarily depends on the unit mass of aggregates used in the mixture. Tests show that the unit weight of the low-calcium, fly-ash-based geopolymer concrete is similar to that of Portland cement concrete. When granite-type coarse aggregates were used, the unit weight varied between 2330 and 2430 kg/m³ (Hardjito and Rangan, 2005).

TABLE 26.4 Geopolymer Concrete Mixture Proportions

Materials	Mass (kg/m ³)	
	Mixture 1	Mixture 2
Coarse aggregates:		
20 mm	277	277
14 mm	370	370
7 mm	647	647

	Steam curing	36	8	2302	49

26.9 Long-Term Properties of Geopolymer Concrete

26.9.1 Compressive Strength

Geopolymer concrete mixture proportions used in laboratory studies are given in Table 26.4 (Wallah and Rangan, 2006). Numerous batches of these mixtures were manufactured over a period of 4 years. For each batch of geopolymer concrete made, 100 × 200-mm cylinders specimens were prepared. At least three of these cylinders were tested for compressive strength at an age of 7 days after casting. The unit weight of specimens was also determined at the same time. Table 26.5 presents the average results for the numerous specimens made from Mixture 1 and Mixture 2 and heat cured at 60°C for 24 hours after casting (Wallah and Rangan, 2006).

To observe the effect of age on the compressive strength of heat-cured geopolymer concrete, 100 × 200-mm cylinders were made from several batches of Mixture 1 (see Table 26.4). The specimens were heat cured in the oven for 24 hours at 60°C. Figure 26.6 presents the ratio of the compressive strength of specimens at a particular age as compared to the compressive strength of specimens from the same batch of geopolymer concrete tested on the 7th day after casting (Wallah and Rangan, 2006). These test data show that the compressive strength increased with age on the order of 10 to 20% when compared to the 7th-day compressive strength. The test data shown in Table 26.5 and Figure 26.6 demonstrate the consistent quality, reproducibility, and long-term stability of low-calcium, fly-ash-based geopolymer concrete.

To study the effect of age on the compressive strength of fly-ash-based geopolymer concrete cured in laboratory ambient conditions, three batches of geopolymer concrete were made using Mixture 1 (see Table 26.4). The test specimens were 100 × 200-mm cylinders. The first batch (May 05) was cast in May 2005, a second batch (July 05) was cast in July 2005, and a third batch (Sept 05) was cast in September 2005. The ambient temperature in May 2005 during the first week after casting the concrete ranged from

FIGURE 26.6 Change in compressive strength of heat-cured geopolymer concrete with age. (From Wallah, S.E. and Rangan, B.V., *Low-Calcium Fly-Ash-Based Geopolymer Concrete: Long-Term Properties*, Research Report GC2, Faculty of Engineering, Curtin University of Technology, Perth, 2006.)

FIGURE 26.7 Compressive strength of geopolymer concrete cured in ambient condition. (From Wallah, S.E. and Rangan, B.V., *Low-Calcium Fly-Ash-Based Geopolymer Concrete: Long-Term Properties*, Research Report GC2, Faculty of Engineering, Curtin University of Technology, Perth, 2006.)

about 18°C to 25°C; this temperature varied from 8°C to 18°C in July 2005 and from 12°C to 22°C in September 2005. The average humidity in the laboratory during those months was between 40 and 60%. The test cylinders were removed from the molds one day after casting and left in laboratory ambient conditions until the day of test. The test results plotted in Figure 26.7 show that the compressive strength of ambient-cured geopolymer concrete significantly increased with age (Wallah and Rangan, 2006). This test trend is in contrast to the effect of age on the compressive strength of heat-cured geopolymer concrete as shown in Figure 26.6.

26.9.2 Creep and Drying Shrinkage

The creep and drying shrinkage behavior of heat-cured, low-calcium, fly-ash-based geopolymer concrete was studied for a period of 1 year (Wallah and Rangan, 2006). The geopolymer concrete mixture proportions used in that study were Mixture 1 and Mixture 2 (see Table 26.4). The test specimens were 150 × 300-mm cylinders, heat cured at 60°C for 24 hours. The creep tests commenced on the 7th day after casting the test specimens, and the sustained stress was 40% of the compressive strength on that day. The test results obtained for specimens made using Mixture 1 and heat cured in an oven are shown in Figure 26.8. The test trends were similar for both Mixture 1 and Mixture 2, heat cured in an oven or

FIGURE 26.8 Total strain and drying shrinkage strain of heat-cured geopolymer concrete. (From Wallah, S.E. and Rangan, B.V., *Low-Calcium Fly-Ash-Based Geopolymer Concrete: Long-Term Properties*, Research Report GC2, Faculty of Engineering, Curtin University of Technology, Perth, 2006.)

FIGURE 26.9 Effect of compressive strength on creep of heat-cured geopolymer concrete. (From Wallah, S.E. and Rangan, B.V., *Low-Calcium Fly-Ash-Based Geopolymer Concrete: Long-Term Properties*, Research Report GC2, Faculty of Engineering, Curtin University of Technology, Perth, 2006.)

steam cured. Test results show that heat-cured, fly-ash-based geopolymer concrete undergoes very little drying shrinkage, on the order of about 100 microstrains, after 1 year. This value is significantly smaller than the range of values of 500 to 800 microstrains experienced by Portland cement concrete.

The creep coefficient, defined as the ratio of creep strain to elastic strain, after 1 year of loading for heat-cured geopolymer concrete with compressive strengths of 40, 47, and 57 MPa is between 0.6 and 0.7; for geopolymer concrete with a compressive strength of 67 MPa, this value is between 0.4 and 0.5. Data for the specific creep, defined as the creep strain per unit of sustained stress, are shown in Figure 26.9; the specific creep values after 1 year of loading are given in Table 26.6 (Wallah and Rangan, 2006). These values are about 50% of the values recommended by the draft Australian Standard AS 3600 for Portland cement concrete.

The drying shrinkage strains of geopolymer concrete cured in ambient conditions are many folds larger than those experienced by the heat-cured specimens (Figure 26.10). As indicated by Equation 26.2, water is released during the chemical reaction process of geopolymers. In the specimens cured in ambient conditions, this water may evaporate over a period of time and cause significantly large drying shrinkage strains, especially in the first 2 weeks, as can be seen in Figure 26.10 (Wallah and Rangan, 2006).

TABLE 26.6 Specific Creep of Heat-Cured Geopolymer Concrete

1CR	67	15
2CR	57	22
3CR	47	28
4CR	40	29

26.9.3 Sulfate Resistance

Tests were performed to study the sulfate resistance of heat-cured, low-calcium, fly-ash-based geopolymer concrete (Wallah and Rangan, 2006). The test specimens were made using Mixture 1 (see Table 26.4) and were heat cured at 60°C for 24 hours after casting; they were immersed in a 5% sodium sulfate solution for various periods of exposure up to 1 year. The sulfate resistance was evaluated based on the change in mass, change in length, and change in compressive strength of the specimens after sulfate exposure. The test specimens were 100 × 200-mm cylinders for change-in-mass and change-in-compressive strength tests and 75 × 75 × 285-mm prisms for change-in-length tests. Test results suggest that heat-cured, low-calcium, fly-ash-based geopolymer concrete has an excellent resistance to sulfate attack. No damage to the surface of test specimens was observed after exposure to sodium sulfate solution up to 1 year, and no significant changes in the mass and the compressive strength of test specimens were observed after various periods of exposure up to one year. The change in length was extremely small and less than 0.015%. The deterioration of Portland cement concrete due to sulfate attack is attributed to the formation of expansive gypsum and ettringite which causes expansion, cracking, and spalling in the concrete. Low-calcium, fly-ash-based geopolymer concrete undergoes a different mechanism from that of Portland cement concrete, and the geopolymerization products are also different from hydration products. The main product of geopolymerization, as given by Equation 26.2, is not susceptible to sulfate attack as are the hydration products. Because of the lack of gypsum or ettringite formation in the main products of geopolymerization, there is no mechanism of sulfate attack in heat-cured, low-calcium, fly-ash-based geopolymer concrete. However, the presence of high calcium either in the fly ash or in the aggregates could cause the formation of gypsum and ettringite in geopolymer concrete.

26.9.4 Sulfuric Acid Resistance

Tests were performed to study the sulfuric acid resistance of heat-cured, low-calcium, fly-ash-based geopolymer concrete (Wallah and Rangan, 2006). The concentrations of the sulfuric acid solution were 2%, 1%, and 0.5%. The sulfuric acid resistance of geopolymer concrete was evaluated based on the mass loss and the residual compressive strength of the test specimens after acid exposure up to one year. The test specimens, 100 × 200-mm cylinders, were made using Mixture 1 (see Table 26.4) and were heat cured at 60°C for 24 hours after casting. The visual appearance of specimens after exposure to sulfuric acid solution showed that acid attack slightly damaged the surface of the specimens. The maximum mass loss of test specimens of about 3% after 1 year of exposure is relatively small compared to that for Portland cement concrete as reported in other studies. As shown in Figure 26.11, exposure to sulfuric acid caused degradation in the compressive strength; the extent of degradation depended on the concentration of the acid solution and the period of exposure.

26.10 Reinforced Geopolymer Concrete Beams and Columns

To demonstrate the application of heat-cured, low-calcium, fly-ash-based geopolymer concrete, 12 reinforced columns and 12 reinforced beams were manufactured and tested (Sumajouw and Rangan, 2006). In the column test program, the primary parameters were longitudinal reinforcement ratio, load eccentricity, and compressive strength of geopolymer concrete. The longitudinal reinforcement ratio was 1.47% and 2.95%. The column cross-section was 175-mm square. The average yield strength of the longitudinal

FIGURE 26.10 Drying shrinkage of heat-cured and ambient-cured geopolymer concrete. (From Wallah, S.E. and Rangan, B.V., *Low-Calcium Fly-Ash-Based Geopolymer Concrete: Long-Term Properties*, Research Report GC2, Faculty of Engineering, Curtin University of Technology, Perth, 2006.)

FIGURE 26.11 Acid resistance of heat-cured geopolymer concrete. (From Wallah, S.E. and Rangan, B.V., *Low-Calcium Fly-Ash-Based Geopolymer Concrete: Long-Term Properties*, Research Report GC2, Faculty of Engineering, Curtin University of Technology, Perth, 2006.)

steel was 519 MPa. Closed ties made of 6-mm-diameter hard-drawn wires at 100-mm spacing were used as lateral reinforcement. The concrete cover was 15 mm. The columns were subjected to eccentric compression and bent in single curvature bending. The columns were pin ended with an effective length of 1684 mm.

The mixture proportions of geopolymer concrete used in the manufacture of the column specimens are given in Table 26.7. The average slump of fresh concrete varied between 210 and 240 mm. The nominal compressive strength of geopolymer concrete was 40 MPa for the GCI and GCII series and 60 MPa for the GCIII and GCIV series. These target compressive strengths were achieved by using the mixtures given in Table 26.7 and by exploiting the flexibilities of the heat-curing regime of geopolymer concrete (see Section 26.6). Accordingly, for the GCI and GCII column series, the test specimens were steam cured at a temperature of 60°C for 24 hours after casting; in contrast, the GCIII and GCIV specimens were kept in laboratory ambient conditions for 3 days and then steam cured at a temperature of 60°C for 24 hours.

The mixture proportions of geopolymer concrete used in the manufacture of the beam specimens are also given in Table 26.7. The average slump of the fresh concrete varied from 175 mm for the GBIII series to 255 mm for the GBI series. The target compressive strength of the geopolymer concrete was 40 MPa for the GBI series, 50 MPa for the GBII series, and 70 MPa for the GBIII series. The specimens were kept in laboratory ambient conditions for 3 days after casting and then steam cured at 60°C for 24 hours to achieve the target strengths. The beam cross-section was 200 mm wide by 300 mm deep by 3300 mm in

TABLE 26.7 Geopolymer Concrete Mixture Proportions for Reinforced Columns and Beams

Materials	Mass (kg/m ³)		
	Columns		Beams
10-mm aggregates	555	550	550

			13.5 (GBIII)

length. The test parameters were concrete compressive strength and longitudinal tensile reinforcement ratio. All beams contained two 12-mm-diameter deformed bars as compression reinforcement and two-legged vertical stirrups made of 12-mm-diameter deformed bars at 150-mm spacing as shear reinforcement. The longitudinal tensile reinforcement ratios were 0.64, 1.18, 1.84, and 2.69%. The average yield strength of tensile steel bars varied between 550 and 560 MPa. The concrete cover was 25 mm. The beams were simply supported over a span of 3000 mm and were subjected to two concentrated loads placed symmetrically on the span. The distance between the loads was 1000 mm.

The behavior and failure modes of the reinforced geopolymer concrete columns were similar to those observed in the case of reinforced Portland cement concrete columns. Typical failure modes of geopolymer concrete columns are shown in Figure 26.12 (Sumajouw and Rangan, 2006). As expected, the load capacity of the columns was influenced by the load eccentricity, the concrete compressive strength, and the longitudinal reinforcement ratio. When the load eccentricity decreased, the load capacity of the columns increased. The load capacity also increased when the compressive strength of the concrete and the longitudinal reinforcement ratio increased.

FIGURE 26.12 Failure mode of reinforced geopolymer concrete columns. (From Sumajouw, M.D.J. and Rangan, B.V., *Low-Calcium Fly-Ash-Based Geopolymer Concrete: Reinforced Beams and Columns*, Research Report GC3, Faculty of Engineering, Curtin University of Technology, Perth, 2006.)

FIGURE 26.13 Crack pattern and failure mode of reinforced geopolymer concrete beam. (From Sumajouw, M.D.J. and Rangan, B.V., *Low-Calcium Fly-Ash-Based Geopolymer Concrete: Reinforced Beams and Columns*, Research Report GC3, Faculty of Engineering, Curtin University of Technology, Perth, 2006.)

The load-carrying capacity of reinforced geopolymer concrete columns was calculated using both a simplified stability analysis proposed by Rangan (1990) and the moment-magnifier method incorporated in the Draft Australian Standard for Concrete Structures AS 3600 (Committee BD-002, 2005) and ACI 318 (ACI Committee 318, 2005). As shown in Table 26.8, the calculated failure loads correlate well with the test values. These results demonstrate that the methods of calculations used in the case of reinforced Portland cement concrete columns are applicable for reinforced geopolymer concrete columns. The behavior and failure modes of the reinforced geopolymer concrete beams were similar to those observed in the case of reinforced Portland cement concrete beams. Figure 26.13 shows the crack pattern and failure mode of a reinforced geopolymer concrete beam. The flexural capacity of the beams was influenced by the concrete compressive strength and the tensile reinforcement ratio. The flexural strength of the reinforced geopolymer concrete beams was calculated using the conventional flexural strength theory of reinforced concrete beams as described in standards and building codes such as the Draft Australian Standard AS 3600 and the ACI 318. The results are given in Table 26.9 (Sumajouw and Rangan, 2006). For beams with tensile reinforcement ratios of 1.18%, 1.84%, and 2.69%, the test and calculated values agreed well. In the case of beams with a tensile steel ratio of 0.64%, the calculated values were conservative, as expected, due to the neglect of the effect of strain hardening of tensile steel bars on the ultimate bending moment.

Mid-span deflection at the service load of the reinforced geopolymer concrete beams was calculated using the elastic bending theory and the serviceability design provisions given in the Draft Australian Standard AS 3600. According to AS 3600, the calculation of short-term deflection of reinforced concrete

TABLE 26.9 Correlation of Test and Calculated Ultimate Moment of Reinforced Geopolymer Concrete Beams

beams should include the effects of cracking, tension stiffening, and shrinkage properties of the concrete. In these calculations, the service load was taken as the test failure load divided by 1.5; measured values of the modulus of elasticity and drying shrinkage strain of geopolymer concrete were used. Good correlation of test and calculated deflections at service load can be seen in Table 26.10 (Sumajouw and Rangan, 2006). In all, the results given in Table 26.8, Table 26.9, and Table 26.10 demonstrate that reinforced low-calcium (ASTM Class F), fly-ash-based geopolymer concrete structural members can be designed using the design provisions currently used for reinforced Portland cement concrete members.

26.11 Economic Benefits of Geopolymer Concrete

Heat-cured, low-calcium, fly-ash-based geopolymer concrete offers several economic benefits over Portland cement concrete. The price of a ton of fly ash is only a small fraction of the price of a ton of Portland cement; therefore, after allowing for the price of the alkaline liquids required to make the geopolymer concrete, the price of fly-ash-based geopolymer concrete is estimated to be about 10 to 30% less than that of Portland cement concrete. In addition, the appropriate usage of a ton of fly ash earns approximately one carbon credit, which has a redemption value of about 10 to 20 Euros. Based on the information given in this chapter, a ton of low-calcium fly ash can be utilized to manufacture approximately 2.5 m³ of high-quality, fly-ash-based geopolymer concrete and hence can earn monetary benefits through carbon-credit trade. Furthermore, the very little drying shrinkage, low creep, excellent resistance to sulfate attack, and good acid resistance offered by the heat-cured, low-calcium, fly-ash-based geopolymer concrete may yield additional economic benefits when it is utilized in infrastructure applications.

26.12 Concluding Remarks

This chapter presented information on heat-cured, fly-ash-based geopolymer concrete. Low-calcium fly ash (ASTM Class F) is used as the source material instead of the Portland cement to make concrete. Low-calcium, fly-ash-based geopolymer concrete has excellent compressive strength and is suitable for structural applications. The salient factors that influence the properties of the fresh concrete and the hardened concrete have been identified. Data regarding mixture proportions are included and illustrated by an example. The elastic properties of hardened geopolymer concrete and the behavior and strength of reinforced geopolymer concrete structural members are similar to those observed for Portland cement concrete; therefore, the design provisions contained in the current standards and codes can be used to

design reinforced low-calcium, fly-ash-based geopolymer concrete structural members. Heat-cured, low-calcium, fly-ash-based geopolymer concrete also shows excellent resistance to sulfate attack and good acid resistance, undergoes low creep, and suffers very little drying shrinkage. This chapter has also identified several economic benefits of using geopolymer concrete.

27.1 Introduction

Concrete structures are difficult to evaluate using theoretical models. These models require precise definitions of material properties, support conditions, and the stiffness of individual members. All of these are difficult to define for concrete structures. Other than compressive strength, test data on material properties are often not available, and when such data are available, they are likely to exhibit considerable scatter. Support conditions are not easily defined, and the stiffness of a cracked concrete member can be difficult to determine with any precision. For most structures, the fact that theoretical models cannot predict structural exact behavior is not a problem. The use of proper safety factors and years of experience

* Professor of Civil Engineering, University of Cincinnati, Cincinnati, Ohio; expert in nondestructive testing and evaluation of existing bridges.

in designing and building concrete structures have led to safe and economical designs; however, for certain structures, theoretical evaluation is inadequate. Structures with suspected design or construction flaws, damaged or deteriorated structures, or with unusual design features require a performance evaluation.

Performance evaluation can be defined as the destructive, partially destructive, or nondestructive physical test of a structure, structural system, or structural subsystem for determining critical responses under one or more loading conditions. Performance testing is used for evaluating service load behavior, determining cracking load or ultimate load capacity, determining stiffness or flexibility, detecting damage or deterioration, and evaluating the effects of the damage or deterioration, the effects of support conditions, fatigue or cyclic load behavior, and response to impact or vibrational loads. Performance tests can be divided into two groups: tests for quality control (including verification of load capacity) and tests to assess structural performance when existing theories are inadequate or nonexistent.

When most people think of performance evaluation, they usually think of strength evaluation—specifically, the method described in the American Concrete Institute's *Building Code Requirements for Structural Concrete* (ACI Committee 318, 2005). This method, discussed in Chapter 20 of the ACI Code, is intended to evaluate structures where there is some doubt that the structure meets the safety requirements of the Code. ACI 437R-03, *Strength Evaluation of Existing Concrete Buildings* (ACI Committee 437, 2003), presents a more in-depth discussion of structural strength evaluation. The report defines several cases where the strength-evaluation techniques discussed in the report may be useful:

- Distressed structures that show signs of damage due to overload, fire, vibration, etc.
- Deteriorated structures that show signs of damage through material degradation such as corrosion, excessive cracking of the concrete, spalling, etc.
- Structures suspected of containing understrength materials or to be substandard in design or construction
- Structures where the capacity to hold loads applied in the future is in doubt because the original design or construction data are not available
- Structures for which a change in usage would apply loads in excess of the original design loads
- Assessment of structures undergoing repair, retrofit, or strengthening
- Structures that require testing by order of a building official

The committee recognizes other areas where performance testing may be valuable but does not recommend using the strength-evaluation method presented in the report for these areas:

- Structures with unusual design concepts
- Product development testing used for approval or quality control for mass-produced elements
- Evaluation of foundations or soil conditions
- Structural research

Other possible areas, not mentioned in the report, where strength or performance testing may be useful include:

- To assess the condition of a structure, especially when hidden damage or deterioration is suspected
- To verify the results of analytical modeling

This chapter attempts to present performance testing in the broadest possible terms.

27.2 ACI 318-08 Provisions on Strength Evaluation of Existing Structures

The method described in Chapter 20 of the ACI Code (ACI Committee 318, 2008) is the one most commonly used for performance evaluation of concrete structures. It makes sense to begin any discussion of performance evaluation with this method. Provisions on the strength evaluation of existing structures

are intended to evaluate the safety of a structure for which the load-carrying capacity is in doubt (Section 20.1). If the effects of the strength deficiency are well understood and the structural dimensions and material strengths are easily verified, analytical evaluation of the structure is permitted (Section 20.1.2); otherwise, load testing is required (Section 20.1.3). If the structural safety is suspect due to deterioration, Section 20.1.4 seems to imply that load testing is also required, as it says that deteriorated structures meeting the load test requirements may remain in service. Section 20.1.4 allows the engineer to require periodic reevaluation if deemed necessary.

If load testing is to be undertaken, Section 20.3 requires the structure to be loaded such that any suspect areas are subjected to maximum stress and deflection. In some cases, a single load placement may not simultaneously maximize all of the critical responses and multiple load placements must be used to demonstrate the adequacy of the structure. The ACI 318-08 Code stipulates that the total load test including dead load already in place should not be less than the larger of the U value determined by Equation 27.1:

$$U = 1.15D + 1.5L + 0.4(L_r \text{ or } S \text{ or } R) \quad (27.1a)$$

$$U = 1.15D + 0.9L + 1.5(L_r \text{ or } S \text{ or } R) \quad (27.1b)$$

$$U = 1.3D \quad (27.1c)$$

where D = dead load, L = live load, L_r = roof live load, S = snow load, and R = rain load. The load factor on live load in Equation 27.1b can be reduced to 0.45 for garages, areas occupied as places of public assembly, and all areas where L is greater than 100 lb/ft².

When conducting a load test, the testing sequence is as follows:

- An initial measurement is taken of the important structural responses: deflections, strains, crack patterns, crack openings, rotations, etc. Of all these responses, only deflection and cracking are used for acceptance, but the provisions recognize that other responses, although not required, may be of interest. These responses must be measured not less than 1 hour before the test.
- The load is applied in four equal increments. Between each increment, structural response is measured. Section 20.4.4 requires the structural responses to be measured after each load increment is applied, and the Commentary (R20.4.2) suggests inspecting the structure after each load increment is applied. No maximum or minimum time limit between applications of the load increments is specified. Section 20.4.3 requires that uniform loads be applied in such a way that a uniform load distribution is obtained. In some cases, loads may be applied incorrectly, resulting in an uneven load distribution. The most common case, cited in the Commentary, is when concrete blocks are used for loading. As the structure deflects, the blocks may rotate and touch at the top, creating an arch. Subsequent loads are carried by these arches, and nonuniform load distributions result.
- When the total load is in place, it is left for 24 hr. Structural response measurements are taken at the beginning and end of this period.
- After the 24-hr period, all structural responses are measured, and the load is immediately removed. The structure is left for 24 hr, and the structural responses are measured at the end of the 24-hr period.

The tested area cannot show any signs of failure. Crushing of the concrete is considered failure.

After removal of the load, the structure must recover at least 75% of the maximum deflection:

$$\Delta_r = \frac{\Delta_1}{4} \quad (27.2)$$

where Δ_r is the deflection 24 hr after removing the load, and Δ_1 is the deflection under load after the load is in place for 24 hr. Because very stiff structures have small deflections, it may be difficult to accurately measure deflection recovery, so the code also accepts a structure if:

$$\Delta_{\max} \leq \frac{l_t^2}{20,000h} \quad (27.3)$$

where l_t is the span of the member (taken as the smaller of center to center of supports or clear span + h) and h is the member thickness. For two-way slabs, l_t is the shortest span.

Structures that fail the deflection part of the test may be retested after 72 hr and accepted if:

$$\Delta_r = \frac{\Delta_2}{5} \quad (27.4)$$

where Δ_2 is the maximum deflection during the second test.

The structure cannot exhibit excessive cracking, spalling, or crushing, which may indicate failure. The structure fails if inclined cracks appear, which may indicate a shear failure. Any inclined cracks in areas of a member without transverse reinforcement must be evaluated if the crack is longer than the depth of the member. For members with a variable depth, the depth at the midpoint of the crack is used. In anchorage zones or in areas where there are lap splices, short inclined cracks or horizontal cracks must be investigated, as these may be signs of a bond or anchorage splitting failure.

It is clear that ACI 318 requirements are narrowly tailored to evaluate structural safety against failure. If other structural responses are desired, such as performance and serviceability under working load, changes in structural response due to damage or deterioration, etc., then broader performance-testing techniques are necessary.

27.3 Pretest Planning for Reliable Structural Evaluation

The most critical phase of performance evaluation is the pretest planning. In this phase, a detailed plan or critical path should be established not only to ensure that the tests are performed correctly but also to be sure that all critical responses are measured. Pretest planning can be broken down into several distinct general tasks:

- *Determine the specific purpose of the test and desired final product.* This is probably the most overlooked part of pretest planning. Prior to beginning the test, the following items should be evaluated:
 - Determine the specific desired outcome. Possible outcomes could be service load behavior, proof of ultimate load levels, or behaviors that may indicate the presence of damage, deterioration, possible deficiencies in materials, or construction flaws. Before beginning any test, it is important to have a clear picture of the final outcome as this determines the choice of test method, load levels, and instrumentation.
 - Determine the test method that best meets the goal. When evaluating a structure, engineers often choose load testing as a first, or only, alternative. In fact, there are many ways to evaluate a structure other than just load testing (e.g., modal testing).
 - If load testing is chosen, be sure the loading method is realistic for the structure. Uniform loads are appropriate for a general structure but are not a good choice for testing bridges as traffic loads tend to be point loads. Be sure the loading method will produce the desired results; for example, due to the difficulty of applying a moving load for many cycles, stationary cyclic loads are often used to simulate repeated traffic loads, although stationary, cyclic loads may not produce the same response as an actual moving load (Petrou et al., 1994).
 - Determine the type of data required to accurately assess the structure. In many performance tests, only deflection is measured, which may not provide sufficient data. Often strains, rotations, differential movements, temperature changes, or accelerations may also have to be measured. Instrumentation should be properly chosen to provide the necessary data.

- *Gather all available design and construction information.* When the purpose of the test has been established, the next step is to gather all available design and construction information to provide a basic background of the structure and a baseline for comparing actual material test results and actual dimensions. Necessary information on design loads, material specification and strengths, design drawings, construction records, as-built drawings, and records of any modifications to the structure must be assembled and carefully examined to form a complete picture of the structure.
- It is important to obtain as much information as possible about the as-built condition of the structure as variations and deviations from the original plans are not infrequent. Obtaining as-built drawings and copies of inspection records is highly recommended.
- Reports on actual material strength are also of great importance, especially in destructive or partially destructive tests. It should be kept in mind that material specifications are usually minimum or maximum properties (as applicable), and the actual materials may have substantially greater or lower properties than required. For example, ASTM A 36 steel has a minimum yield strength of 36 ksi, but in reality the yield strength can be much higher, with values of 50 ksi not being unusual.
- *Conduct a pretest inspection of the structure and material sampling.* For many structures, the construction records may be inadequate. The records have been lost or destroyed or the inspections may have been insufficient, so detailed inspection and construction records do not exist. In such cases, a pretest inspection of the structure is necessary.
- The structure should first be checked to verify all dimensions. Several measurements of member sizes should be taken at critical sections. Where possible, member support conditions should be checked. At this time, a detailed survey of surface and visible defects should be made. ACI 201.1R-97, *Guide for Making a Condition Survey of Concrete in Service* (ACI Committee 201, 1997), provides a good method for making such a survey.
- Reinforcing bar size, spacing, and cover should be documented. Three common nondestructive methods for measuring the reinforcing bar size, cover, and spacing are magnetic, radiographic, and radar (ACI Committee 437, 2003; Malhotra and Carino, 2004). Bar size and location can also be found by removing the cover in isolated areas. This last method is often used to calibrate nondestructive testing (NDT) methods. Where practical, bar samples should be removed for further evaluation, including strength tests and assessment of the degree of corrosion, if present.
- Concrete strengths are normally determined by coring (ASTM, 2004a), as this seems to be the only accurate method for determining in-place concrete strength. Guidance on using cores to determine in-place strength is found in ACI 214.4R-03 (ACI Committee 214, 2003). Nondestructive tests for determining concrete compressive strength include the rebound hammer or probe penetration, but these methods do not directly measure strength, and they show a high degree of variability, especially when different types of concrete are being tested. As a result, the methods require calibration with drilled cores for each type of concrete being tested, and even then they are of questionable accuracy. Tensile strengths can be found by performing the split cylinder test (ASTM, 2004b) on cores or by use of sawed beams (ASTM, 2004a), if practical.
- In addition to cores removed for strength testing, cores should also be taken for petrographic (ASTM, 2004c) or chemical testing. Petrographic and chemical testing can reveal potential weaknesses in the concrete due to alkali-silica reaction (ASR), inhomogeneity, bleed, or segregation; poor air-void systems that allow freeze-thaw damage (ASTM, 2006); reinforcing steel corrosion; abrasion; fire; D-cracking of aggregates; and weathering. It is also necessary to sample and test auxiliary materials such as overlays, bearing pads, material in attached structures, etc. This is especially necessary when such materials may affect loading, boundary conditions, and structural or material behaviors.
- When sampling the material, the question arises as to how many samples are necessary to yield reliable results. The answer to this question is based on the practicality of sampling the material and the amount of error that can be tolerated. In general, the number of samples is affected by the following: (1) The amount of possible damage that would occur when samples are

removed; the attraction of nondestructive testing is that any number of samples can be taken without damaging the structure. (2) The cost, in money and time, to perform the test; often testing must be limited due to time and budget constraints. (3) The importance of the data; for example, the flexural strength of reinforced concrete is only slightly affected by the compressive strength so less accuracy can be tolerated in determining the compressive strength of a flexural member. On the other hand, the strength of axial members is greatly influenced by compressive strength, so a more accurate determination of compressive strength is necessary. To determine the number of samples required, any of a number of statistical techniques can be applied. ASTM C 823 provides information on developing a program for material sampling (ASTM, 2000).

- *Perform a pretest analytical investigation.* The data collected from records and inspection can be used to create an analytical model of the structure. This model will provide necessary information for designing the test. In the case of load tests, the model will provide information on probable cracking, yield, and ultimate load capacities. The model can also be used to pinpoint critical responses so the instrumentation can be properly placed to record these responses during the actual test. In the case of dynamic tests, frequencies, accelerations, magnification (impact) factors, and vibrational mode shapes can be estimated from the model.
- *Design the testing and instrumentation system.* The test can be designed using the results from the model. In the case of load testing, it is necessary to choose the type of load, load levels, load position, and method of loading (e.g., trucks, blocks, hydraulic). Load-reaction frames for hydraulic-loading cylinders also have to be designed at this point.
- *Lay out instrumentation grids based on the analytical results so the instruments are in place to capture critical responses.* The model results are also used to estimate the magnitude of the response so an instrument with a proper range and accuracy is chosen (see Section 27.6). The data acquisition systems should be chosen at this time.
- *Perform the test and evaluate the results.* With a properly designed test, performance of the test becomes a relatively simple task. Time spent up front in planning will greatly reduce the chance of problems occurring during the test and will lead to a successful outcome.

Unfortunately, evaluation of the results is not an easy task. Even in tests that have excellent pretest planning, ambiguities in the data often must be reconciled. In such cases, it is useful to create post-test models to assist in data evaluation.

27.4 Nondestructive Testing for Material and Structural Assessment

In pretest evaluation, it is necessary to carefully evaluate the condition of the material and the structure. Some of the previously stated methods are partially destructive or inspect only a small portion of the structure. For large-scale detection of flaws, other methods are needed. Of the many nondestructive methods for evaluation of concrete structures, only a few are presented here. A complete treatment of NDT methods can be found in Malhotra and Carino (2004).

27.4.1 Ultrasonic Testing

Sound waves have been used for testing concrete for many years. Many states still employ the *chain-drag* method for concrete bridge decks. A large metal chain is dragged across the concrete surface, subjecting the surface to small impacts, and delaminations in the concrete are found when a hollow sound is heard during the dragging of the chain. The limitations of this method are obvious: It only detects flaws near the surface, an experienced person who can differentiate the sounds is needed, and it cannot provide numerical data on the size and depth of the flaws. More modern methods of testing concrete utilize

ultrasonic waves transmitted through the concrete. A simple ultrasonic test, the *pulse-velocity test*, consists of creating an ultrasonic pulse, detecting the same pulse at a remote receiver, and measuring the time it takes for the pulse to travel the distance. Changes in the pulse transmission time can represent changes in the properties of the concrete; for example, as young concrete gains stiffness, the pulse transmission time decreases. Increases in pulse transmission time often indicate the presence of damage, as the pulse cannot transmit through a crack and instead must take a longer path around the damaged area. The *impact-echo* technique provides a more quantitative measurement of flaws in the concrete (Carino and Sansalone, 1992; Carino et al., 1986). In this method, a small impactor is used to create a wave in the concrete. When the wave hits an interface, either a free surface or a crack, it is reflected back to a receiver. By processing the returned signal, the depth and size of flaws can be determined (Carino and Sansalone, 1992).

27.4.2 Infrared Thermographic Testing

Infrared thermographic testing works on the principle that flaws in concrete will affect the way in which heat flows through the concrete. This, in turn, affects the surface temperature distribution. The concrete is either heated up or cooled down, and surface is photographed using a camera that is sensitive to infrared radiation. Damage to the concrete is seen as cooler or hotter areas (Delahaza, 1996; Weil, 1993). Often, simply allowing a concrete structure to heat up during the day due to sunlight or to cool down at night produces sufficient temperature variations to make infrared thermographic techniques usable. One advantage to the thermographic method is that it can be used in a moving system to examine pavements without having to stop or detour traffic. Several case studies outlining the use of thermographic testing for pavements are given by Weil (Malhotra and Carino, 2003).

27.4.3 Modal Testing

When evaluating a concrete structure, it is beneficial to have information about the actual stiffness or flexibility of the structure. Changes in flexibility over time can be used as a measure of global deterioration, and local changes in flexibility can be used to pinpoint local damage. For modeling purposes, the accuracy of a model can be determined by comparing the actual flexibility of the structure with the flexibility obtained from the model. One method of determining the actual flexibility of a structure is polyreference modal testing. Modal testing can be used by itself as a nondestructive method of structural evaluation. It can also be used as a pretest evaluation procedure for planning a load test of a structure, as modal testing can identify damaged, deteriorated, or suspect areas of the structure (Aktan et al., 1992). After the load test, the flexibility matrix obtained from modal testing can be used to verify the results of the load test and to calibrate finite-element models.

In the modal-testing method, structural vibrations are produced by an impact (Aktan et al., 1992; Allbright et al., 1994). (Forced vibrations have also been used, but this method is more complex so only the impact method will be discussed here.) The structural vibrations resulting from the impact are then measured by seismic accelerometers. By knowing the time histories of the impact (measured with a load cell) and the corresponding accelerations distributed through the structure, the modal frequencies, modal vectors, and damping can be calculated. Modal testing offers the advantage of not having to calculate the mass and stiffness of the member; instead, vibrational characteristics are measured and used directly. From the magnitude and frequency of the vibrations, the natural mode shapes and frequencies can be determined, and these can be used further to calculate a flexibility matrix.

Prior to conducting a modal test, an approximate theoretical or finite-element analysis should be made to provide a clear understanding of the structure for the purpose of establishing impact points and accelerometer (reference) points. The results of approximate theoretical or finite-element analysis are used so the accelerometers are not placed at grid points that would correspond to the nodes of the first few significant modes. The analysis is also used to establish the bandwidth of expected frequencies, which is necessary so the dynamic data acquisition system will read only within the band of frequencies of interest.

In theory, the test can be performed with a single accelerometer, but in practice a minimum of three noncolinear reference points are used, although more reference points will often provide better data (Aktan et al., 1992; Allbright et al., 1994). Impact to the structure is supplied either by a sledgehammer or a falling weight. In both cases, the impactor must be instrumented with a load cell so the exact impact load time history is known. Instrumented hammers are commercially available. Each grid point (including the reference points) undergoes impact, and the resulting vibrations are measured by the accelerometers. The impactor load cell and the accelerometers are read using a dynamic analyzer (these are also commercially available). A fast Fourier transform (FFT) is used to transform both the input (impactor) data and the output (accelerometer) data from the time domain into the frequency domain. The frequency response function (FRF), which is basically the ratio of the output FFT to the input FFT, is then calculated. The calculation of the FFT and FRF will normally be performed by the dynamic analyzer, although the operator should have some degree of expertise to ensure the quality of the final data.

When impacts are applied to the structure, care must be taken to ensure that the impactor does not bounce and create multiple impacts while the acceleration data are being taken, as this would corrupt the acceleration data. Also, in some cases, the impact is too hard or too soft and the resulting data are outside the range of the data acquisition system. Such tests should be discarded and redone. This is why it is essential to use a dynamic analyzer capable of processing the results in real time.

Each time a point is struck and acceleration data are taken, a single dataset is created for that point; however, one dataset per impact point is not enough to yield reliable results, so each point is tested several times to collect multiple datasets, the results of which are then averaged. In general, it is necessary to have at least five good datasets per point. When the dynamic data have been obtained for all impact points, they can be transferred to a commercial program that will then calculate the modal frequencies, modal vectors (mode shapes), and damping. Anomalies in the frequencies or mode shapes can sometime be used to identify damage (Allbright et al., 1994), but the flexibility matrix is usually required for an accurate evaluation:

$$[F] = [\psi] \left[\frac{1}{\omega^2} \right] [\psi]^T \quad (27.5)$$

where:

$[F]$ = flexibility matrix.

$[\psi]$ = unit-mass scaled modal vectors.

$[1/\omega^2]$ = diagonal matrix of ascending natural frequencies.

A method for calculating the flexibility matrix from mass-scaled modal vectors can be found in Catbas et al. (1997).

Modal testing does not provide an exact flexibility matrix, as an infinite number of modes would be required to calculate the exact flexibility; however, if a sufficient number of modes can be detected, the modal flexibility matrix can be close enough to the actual flexibility to provide highly accurate results. When the modal flexibility matrix has been obtained, it can be used to evaluate the structure:

$$[P][F] = [\delta] \quad (27.6)$$

where:

$[P]$ = vector of point loads placed at impact points.

$[F]$ = modal flexibility matrix.

$[\delta]$ = vector of displacements at impact points.

Any loading pattern can then be simulated by placing point loads at the corresponding impact points. (A uniform load is simulated by placing point loads at all impact points.) This shows one of the advantages of modal testing. Often, damage to a structure is localized and can only be detected through load testing if the load combination and load placements are ideal to reveal the damage. In a real load-test situation,

this would require an unrealistic number of load cases; however, with the modal flexibility matrix, a large number of loading patterns can be efficiently checked to see if any damage is detected. For damage detection, it is best to have a baseline modal flexibility matrix of the undamaged structure. Damage can then be detected by comparing deflections from subsequent modal flexibility matrices to deflections found from the baseline matrix. If a baseline matrix is not available, deflections found from the modal flexibility matrix can be compared to deflection generated from an idealized model of the undamaged structure (e.g., finite-element model), but this comparison is less accurate. Finally, the modal flexibility matrix can be used to fine-tune the stiffnesses and boundary conditions of a finite-element model. Here, the deflections generated from the model are compared to those generated from the modal flexibility matrix, and the model is adjusted to obtain the best comparison for several load cases. The tuned model can then be used for analysis of the structure.

27.5 Static/Quasi-Static Load Testing

Static/quasi-static load testing is the most common form of structural testing. Because many structural loads are static in nature, a static or monotonic quasi-static load test can provide valuable information on stress, strain, load distribution, and deflection under normal loading conditions. Quasi-static cyclic loading is often used to assess fatigue behavior. For moving or dynamic loads, cyclic quasi-static load testing is sometimes used as a simpler or less expensive alternative to using actual moving or dynamic loads; however, the validity of using cyclic quasi-static loading to evaluate moving or dynamic loads is questionable (Chung and Shah, 1989; Petrou et al., 1994).

27.5.1 Use of Dead Loads

One method of conducting static-load test consists of placing a dead load on the structure. Typical dead loads are concrete blocks, bricks, sandbags, or containers of gravel, sand, or water. The advantages of using dead loads are as follows:

- They can easily simulate a uniform load on a structure. A single layer of 200-mm (8-in.) hollow-core concrete blocks with 25-mm (1-in.) gaps in between to prevent arching can provide a uniform load of 1.4 kN/m² (29 psf).
- The loading materials are relatively inexpensive. In many cases, bricks, blocks, crushed stone, or sand can be borrowed from building supply yards or quarries.

The disadvantages of this type of testing are numerous and often relate to safety:

- Except for exposed structures such as roofs or bridges, the dead load often cannot be placed remotely (as by crane) and must be placed by hand. This presents a danger to workers should the structure fail while load is being applied.
- Should the structure begin to crack or collapse, the loads cannot be removed quickly or safely enough to prevent additional damage or complete collapse.
- Should the structure completely or partially collapse, the load may fall freely and perhaps injure workers or unintentionally damage other parts of the structure.
- The actual load on the structure can only be assessed through the cumbersome process of weighing the individual loading blocks or containers, and there is no easy way to record the load on modern data acquisition systems.
- This method cannot be used to simulate moving or fatigue loads.

For safety reasons, dead load testing should be limited to service load tests well below damage or collapse limit states. ACI 437R-03 (ACI Committee 437, 2003) allows the use of dead load testing but, because of safety issues, does not recommend it. When using dead loads, several practices should be observed. All loading blocks or containers should be of the same weight; ACI Committee 437 allows a

±5% variation between individual units. The loads should be placed with gaps between the individual loading blocks or containers. This is because the structure will deflect under load, and if the loading blocks or containers are too close together they may touch and form an arch. The arch formations make the actual loading pattern uncertain. Loose material (sand, gravel, water) should not be used for load testing as it may gather in low areas of the structure and pond, again creating an uncertain loading pattern. Any loose material used for loading should be placed in containers and the full containers used to apply the load.

27.5.2 Vehicle Testing

Vehicle testing is preferred for service load testing of structures such as bridges or parking decks where vehicle loads are the predominant live loads. Vehicles can be empty or loaded with sand or gravel; thus, loaded dump trucks are very effective for applying loads (Aktan, et al., 1993; Dimmerling et al., 2005; Shahrooz et al., 1994a,b). Vehicle axle or single wheel weights can be obtained using truck scales such as those found at concrete plants, building supply yards, or highway department weigh stations. Many state highway patrols have portable scales that can be used. Vehicular load testing has several advantages:

- It is the type of load that would exist on bridges, parking decks, garage floors, etc. in service load conditions.
- Because trucks can often be supplied by highway departments or local contractors and the sand or gravel to load them can be borrowed from concrete plants or building supply yards, vehicular loading is a relatively inexpensive testing method.
- Vehicular loading can be used to apply static, moving, or impact loads to a structure.

The disadvantages include:

- As with dead loads, vehicle loading requires workers (drivers, in this case) to actually place the load on the structure. Although movable, vehicular loads usually cannot be removed quickly enough to prevent injury to the drivers in the event of sudden cracking or collapse.
- Dump trucks are often used for vehicle loadings as they are usually available from contractors or state departments of transportation. Most structures designed to carry vehicles are usually designed to carry vehicles much heavier than a typical dump truck. In many cases, even a large number of fully loaded dump trucks may not be heavy enough to cause large structural responses. It may be necessary to use large trucks loaded with very heavy loads (such as concrete blocks) to obtain a large enough response to be meaningful (Issa et al., 1996).
- It is very difficult to apply the load in increments, as this would require slowly adding load to the vehicle.
- Due to possible clearance problems, it may be difficult to place the loads close together or near barriers.
- If multiple vehicles are used, it is extremely difficult to attain the same axle loads on all of the trucks, even if similar trucks are used. In addition, the loads tend to shift during testing, affecting the axle loads.
- Unless the vehicles are turned off, engine vibrations will affect the test results.
- The load cannot be recorded electronically.

27.5.3 Testing Using Servohydraulic Cylinders

Hydraulic testing consists of applying load through one or more hydraulic cylinders or actuators. This type of loading is preferred (ACI Committee 437, 2003), as it is the safest method. Hydraulic loading can be as simple as using jacks controlled through hand-operated pumps or as complicated as using sophisticated electronic, servohydraulic systems that use electric pumps and computerized controls. The advantages of hydraulic loading include:

FIGURE 27.1 Use of post-tensioning tendons as a loading system.

- Hydraulic tests are safer. Loads can be placed on the structure via a remote-control mechanism, thus keeping workers safe should the structure collapse. Also, electronic hydraulic systems can be equipped with fast unloading circuits and safety shutdowns that will quickly remove all loads at the first signs of collapse.
- In a load-control test where a structure is subjected to predetermined increasing or decreasing increments of loads, a hydraulic-loading system can precisely control load increment, total load, and rate of load application.
- Use of servohydraulic, closed-loop control allows the use of displacement or strain-controlled tests, which are more stable than load-control tests and less likely to result in sudden collapse. This type of testing will often allow post-peak behaviors to be obtained.
- Hydraulic testing is the most efficient way to apply cyclic or fatigue loads.

The disadvantages of hydraulic testing include:

- Hydraulic systems apply point loads. Application of a line load or a uniform load over a small area can only be done using loading blocks or a spreader device (Azizinamini et al., 1992; Miller et al., 1994). Hydraulic systems usually cannot be easily adapted to apply a uniform load over a large area.
- Computer-controlled servohydraulic systems and the associated control systems are expensive to purchase, maintain, operate, and transport.
- Skilled technical people are often required to handle the hydraulics and electrical work to assemble the system.
- A reaction mechanism is necessary for the hydraulic system to push or pull against.

The need for a reaction mechanism is the biggest drawback of hydraulic systems. In some cases, another part of the structure can be used as a reaction frame, but doing so introduces the possibility of unintentional damage to other structural members. In many cases, a reaction frame tied to a foundation or a self-equilibrating testing frame can be built (Azizinamini et al., 1992). Another approach, shown in Figure 27.1, is to use post-tensioning tendons grouted into the soil or rock below the structure (Miller et al., 1994).

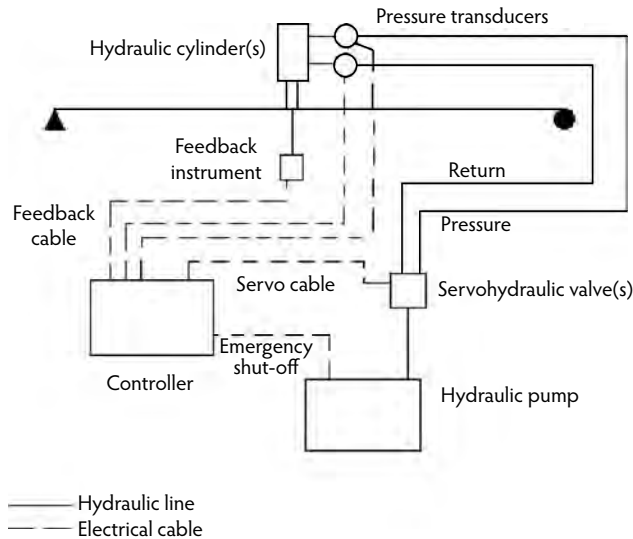

FIGURE 27.2 Closed-loop system.

Hydraulic-loading systems can be precisely controlled through the use of servohydraulic, closed-loop testing. In closed-loop testing, the structure is loaded such that some specific parameter (e.g., load, deflection, strain) increases or decreases at a set rate. To understand the usefulness of the closed-loop servohydraulic system and its limitations, it is first necessary to understand how such a system works. A schematic of a typical closed-loop system is shown in Figure 27.2.

The system consists of five parts: a pump, a servohydraulic valve, a hydraulic actuator, a feedback instrument, and a controller. The pump supplies hydraulic fluid at a set pressure up to a maximum flow rate. The rate of flow of the hydraulic fluid is controlled by a servoelectronic (“servo”) valve, which is a high-speed, proportional valve capable of quickly and precisely varying the flow of hydraulic fluid through the system. The flow rate through the valve is directly proportional to the current input to the valve by the controller.

The hydraulic actuator is a hollow cylinder fitted with a piston and rod. To apply load, hydraulic fluid is pumped into a chamber behind the piston. Some actuators are dual action, meaning fluid can be pumped into a chamber on either side of the piston so the actuator can exert force in either direction. It is important to note that actuator capacities are based on the area of the piston and the maximum pressure supplied by the pump. Quoted actuator capacities are usually based on a 21-MPa (3000-psi) pump pressure. If the pump being used in the test has a maximum pressure different than that given in the actuator manufacturer’s specifications, the quoted capacity will be different. Also, because one side of the piston has the rod attached (thus reducing the area), actuator capacities are different in each direction.

During operation, fluid is pumped into the chamber on one side of the piston. If the actuator is dual action, the chamber on the other side of the piston is opened to allow fluid to flow out. If the rod is attached to a flexible structure, pumping fluid into the chamber produces a combination of pressure in the chamber (which translates to load on the structure) and movement of the piston, which translates to deflection of the structure. Unloading is accomplished by releasing fluid and pressure from the active chamber and pumping fluid into the other chamber.

The load applied by the actuator can be accurately measured by measuring the hydraulic fluid pressure and multiplying by the piston area. This method can often be more accurate and less cumbersome than placing a load cell between the actuator and the structure. Pressure can be measured by pressure transducers that can be directly linked into a computer data acquisition system. In dual-action actuators, there is fluid on both sides of the piston, and both chambers have pressure; therefore, when attempting to calculate load, the differential pressure between the two chambers must be used.

The feedback instrument is any electronic instrument that can read the desired structural response (e.g., deflection) and translate it into a voltage. The controller uses the signal from the feedback instrument to regulate flow through the servovalve. Normally, the controller is set to regulate two things: the rate of the structural response and the maximum value of that response.

For the sake of example, assume that the system shown in Figure 27.2 is set to be a displacement-controlled test of a beam; that is, the system will control the load such that the beam deflects at a set rate up to some predetermined maximum deflection. Initially, the controller is used to pump some fluid into the actuator, and a small load is applied to the beam. An electronic instrument on the beam reads the deflection and converts it to a voltage that is transmitted to the servohydraulic controller. The controller, which is programmed to convert the voltage back to displacement, checks the rate of deflection against the target rate. If the rate of deflection is too slow, the controller will attempt to increase the flow to the hydraulic actuator to increase the loading rate and therefore the deflection rate. If the deflection rate is too fast, the controller will attempt to decrease or, if necessary, reverse the flow to the hydraulic actuator to slow the deflection rate.

When the beam reaches the target maximum deflection, the controller stops the flow to the actuator; however, the system always has some electrical and mechanical noise, so a servohydraulic system will not hold at the specified target but will oscillate about it. This oscillation will introduce noise in the response of the instruments attached to the structure, often giving the responses a sawtooth appearance. Oscillations of the system can also be caused by backlash in the control instrumentation. Backlash is a measure of the change in response necessary to elicit a change the instrument reading when the response is reversed (see Section 27.6). Noise in the system will usually cause the controller to slightly overshoot the intended target response (e.g., deflection, strain), so the controller will unload slightly to correct this condition; however, if the instrument has significant backlash, the response under unloading may not be detected immediately. The controller will miss the target and then attempt to correct by reloading. Thus, instruments with significant backlash will cause large oscillations in the system and should be avoided.

Servohydraulic systems provide an excellent means of conducting a controlled test of structures or elements. These systems, however, are extremely complicated, and a high level of expertise is required to design, build, and operate such systems; therefore competent control engineers should be retained to design and operate servohydraulic systems.

27.6 A Discussion of Instrumentation and Data Acquisition

The importance of instrumentation in a structural test is often overlooked. There is a tendency to assume that the instruments and any associated equipment for data acquisition are transparent; that is, the data coming from the instruments are not affected by the instrumentation itself or the data acquisition system. This is not true. Each instrument, whether a simple mechanical dial gauge or a sophisticated electronic device, has its own particular characteristics that can affect the test results. It is only when the test is complete and the data are found to be faulty that any problems with instrumentation are even considered.

27.6.1 Important Issues in Instrumentation Selection

When selecting instrumentation for a performance test, several issues must be addressed.

27.6.1.1 Range

It is useful to speak of the range of the instrument in terms of *total range* and *working range*. Total range is the maximum and minimum values of input that the instrument can read. Working range is the anticipated maximum and minimum values of response which will be measured during the test. It is normally desirable for the working range to be about 50% of the total range. If the working range is too close to the total range, any error in estimating the maximum or minimum responses may cause the instrument capacity to be exceeded. Some instruments exhibit nonlinearities or other errors near the limits of the range, so measurements near these limits should be avoided. Having a working range that

is very much smaller than the total range is also undesirable. Because the precision of the instrument is normally a function of the total range, trying to make small measurements with an instrument with a large range will usually provide imprecise results.

27.6.1.2 Precision

Precision is a measure of how reproducible a measurement is. Note that precision is an absolute number. A measurement can be precise, but incorrect (or inaccurate). If an instrument has the same error in each measurement, the results may all be within a narrow band, and therefore precise; however, if the average value is not close to the true value, the measurement is precise but inaccurate.

27.6.1.3 Accuracy

Accuracy can be defined as the difference between the instrument reading and the true quantity being measured. Determination of the accuracy of an instrument is a complex and difficult process that requires careful calibration of the instrument. The instrument accuracy is actually the sum of several instrument effects and errors. In general, the response of any instrument can be separated into five components, although for a given instrument some of these responses may not be present. The components are given by:

$$X_{\text{total}} = X_1 + X_2 + X_3 + X_4 + X_5 \quad (27.7)$$

where:

- X_{total} = total instrument response.
- X_1 = response due to the load.
- X_2 = response due to non-load effects on the structure.
- X_3 = instrument error.
- X_4 = error due to external effects on the instrument.
- X_5 = error due to effects of instrument mounting.

In most cases, the total response of the instrument is assumed to be only the caused load, and the other responses are ignored. This can be a grievous error. It is necessary to remove, minimize, or at least account for the other responses of the instrument. The response due to non-load effects (X_2) includes such things as changes in strain and deflection due to temperature. These effects can be significant, as previous research has shown that changes in load distribution, strains, and deflections of an exposed structure due to temperature can be greater than the response due to load (Miller et al., 2004). It is possible to correct for non-load effects by analytical estimation of the values of these effects, by placing additional instrumentation designed to specifically measure non-load related effects, or by performing tests under no applied load to specifically measure these effects.

Every instrument has a certain amount of error associated with its measurements, given by the X_3 term in the previous equation. The data acquisition system itself can cause additional sources of error. When considering the sources of error due to the instrumentation and data acquisition system, it is necessary to consider the following:

- **Resolution**—Resolution is what most people are referring to when they speak of accuracy, but it is only one component of the total accuracy of the instrument. Resolution is the smallest value of a response that can be registered by the instrument. For mechanical gauges, this is the smallest value, a single tick mark. It is possible to interpolate between two marks, but this not objective as it depends on the person reading the gauge. For gauges with digital displays, the resolution is the smallest value on the display. Resolutions of analog electrical instruments are more difficult to determine. In theory, these instruments have infinite resolution but in practice the resolution is limited by the resolution of the digital data acquisition system, electrical noise, and the behavior of the mechanical components within the gauge. Thus, for analog electrical instruments the resolution is the smallest response that provides a reliable reading from the gauge.

FIGURE 27.3 Definition of sensitivity, linearity, hysteresis, and backlash.

- **Sensitivity**—Sensitivity is the output of an instrument for a given input and is expressed as the ratio of output to input (Figure 27.3). Usually, sensitivity is determined by a best-fit straight line. For electrical instrumentation, the output is often influenced by the excitation applied to the instrument, so this is included in the sensitivity. As an example, consider an instrument that measures displacement and output voltage and is excited by a voltage. The sensitivity may be expressed as X volts/volt/mm. This means that a movement of 1 mm will cause the instrument to output X volts if a 1-volt excitation is used. If a 10-volt excitation is used, a 1-mm movement would output $10X$ volts. Sensitivity does not affect accuracy through the instrument itself, but rather through the data acquisition system. If an instrument has a small sensitivity, the output will be small, and the data acquisition system may not be able to read small quantities accurately. Also, small outputs in electrical instruments are often affected by noise.
- **Linearity**—Many instruments (although not all) are assumed to be linear; the output of the instrument has a linear relationship with the response. The linearity error is the measure of how far the data deviate from the best-fit line (Figure 27.2).
- **Repeatability**—Repeatability is the ability of the device to output the same value for the same response over a number of trials when the response is always increasing or decreasing (e.g., always extending the instrument, always heating the instrument) (Figure 27.3).
- **Hysteresis and backlash**—Hysteresis is the difference in a reading at a given point depending on whether the reading was obtained by an increase or decrease in response (e.g., the difference in response when a given point is reached by extending an instrument as compared to the response at the same point reached by contracting the instrument). Backlash is related to hysteresis and is a measure of the change in response required to elicit a change the instrument reading when the response is reversed (e.g., extension to retraction, load to unload, heating to cooling) (Figure 27.3).

Accuracy problems related to resolution and sensitivity can be avoided by proper selection of instruments based on reasonable estimates of the quantities to be measured. Again, this points to the need to perform proper pretest planning. The remaining errors—linearity, hysteresis/backlash, and repeatability—determine the maximum total error of the instrument. Linearity is found by providing a series of inputs over the range and plotting the input against the output (Figure 27.3). For best results, inputs should be made in both directions (e.g., extension and retraction, loading and unloading). At least three trials in each direction should be made and the results plotted on a single graph. The maximum distance from a best-fit straight line to any data point is the maximum total linearity error. Hysteresis/backlash is found by providing input to the instrument through the range in one direction and then providing input through the same range in the reverse direction. The maximum hysteresis/backlash error is the maximum distance between any two points, one in each direction, corresponding to the same input (Figure 27.2). Again, at least three trials should be used. To assess repeatability, input is provided to the instrument through the range but always in the same direction. Maximum repeatability

error is the maximum distance between any two points corresponding to the same input but on two different trials (Figure 27.3).

The X_4 term relates to error in the system introduced by external forces. Two major sources of these errors are drift and noise. Drift is the condition where the instrument reading changes even though the response being measured does not. Drift is often caused by temperature. Noise is a random fluctuation in the instrument output. In electrical instrumentation, noise is typically caused by external electromagnetic sources, such as power lines or electric lights.

The final term, X_5 , is the error associated with the instrument mounting. These errors include misalignment, random environmental vibration of the mounts, creep of the epoxy or glue used to hold the mounting bracket, slip of mechanical mounting, etc. Most of these errors can be eliminated by careful choice of mounting hardware, proper installation, and shielding the instruments from wind and vibrations.

27.6.2 Types of Instrumentation

A large number of different instruments can be used for measuring structural responses. These range from surveying instruments used to measure large deflections to strain gauges accurate to 1×10^{-6} . Each type of instrument has particular uses, accuracy, and limitations. Clearly, it is not possible in the limited space available here to cover all of the possible types of instruments that can be used. A more comprehensive coverage of instruments can be found in Dunnicliff (1993). Although Dunnicliff's work is aimed at geotechnical applications, many of the instruments listed are usable for concrete applications. What follows is a description of some instruments commonly used for concrete.

27.6.2.1 Mechanical Gauges

Mechanical gauges provide an easy, reliable, and inexpensive method for measuring displacement and strain or distortion; however, the use of these gauges is extremely labor intensive and error prone because the gauges must be read manually. This exposes the workers to hazards, leads to possible errors in recording the data, and requires a large workforce or a large amount of time to read all of the gauges. Among the many types of mechanical gauges, the two most common are the dial gauge and the portable strain/distortion gauge (Figure 27.4). Dial gauges consist of a rod attached to a dial by a gearing system. As the rod moves, the movement is registered on the dial. These gauges have various ranges and accuracies. The accuracy of the dial gauge is somewhat difficult to assess. They can be reliably read to the nearest tick mark on the analog dial, but users frequently attempt to interpolate between marks. This adds a degree of subjectivity to the data. Also, the analog gauges are easy to misread, leading to error. Some more modern dial gauges replace the mechanical dial with a digital display, thus reducing these errors. Finally, even the best jeweled movement in the gearing system will exhibit some stick (backlash), making small measurements difficult. Although a dial gauge may respond to dynamic motions, it is impossible to read accurately under these conditions. It is therefore usable only under static or low-frequency cyclic testing. The main advantages of these instruments is that they are easy to use, easy to read, and require no auxiliary equipment (data acquisition systems). They are also inexpensive, especially if the gauges are purchased through a machinery supply house rather than from a scientific supplier.

The portable distortion/strain gauge consists of a metal bar, two points, and a dial gauge (Figure 27.4). One point is fixed; the other point is attached to the dial gauge and is movable. Two targets, pieces of metal with drilled holes, are attached to or embedded in the concrete at the basic length of the gauge. A zero reading is obtained by placing the points of the gauge into the holes in the targets and reading the dial gauge. Subsequent measurements are taken in the same way and the differential movement is found by subtracting the zero reading. This instrument is particularly useful for measuring over large gauge lengths. For smaller gauge lengths, Vernier calipers or micrometers can be used. The portable distortion/strain gauge is also useful in cases where a permanently mounted gauge is impractical. This method is often used to measure strains when conducting long-term creep tests (ASTM, 2002). Bodocsi et al. (1993) used this type of gauge to measure seasonal movements of pavement joints. The portable distortion/strain gauge has the same problems as the dial gauge, but also has the additional problem that the accuracy

FIGURE 27.4 Portable strain gauge.

is dependent on how well the points sit in the holes in the targets. In general, there is always some play in the interface so the measurements are often not repeatable. For this gauge, it is best to take several measurements and average them. Because the gauge must be manually placed to take measurements, it is only usable for static or quasi-static tests.

27.6.2.2 Electrical Instrumentation

Electrical instrumentation has greatly improved the ability of the engineer to safely and accurately monitor structural response. These instruments have the advantage that they can be remotely monitored such that the workers never have to enter the structure during the test. This also allows engineers who cannot be present during the test to monitor the test results in real time from distant locations. Electrical instruments also have the advantage of directly sending all data to computer files, thus reducing data transcription time and errors. Many data acquisition programs allow the instrument responses or mathematical permutations of these responses to be plotted in real time so load–deflection, load–strain, or stress–strain graphs can be plotted while the test is being conducted. One major disadvantage of electrical instrumentation is that these instruments tend to cost much more than similar mechanical instruments. They also require expensive auxiliary equipment, such as data acquisition systems and cables. The biggest drawback, however, is the need for electrical power, which is not always available at remote sites. Where power is not available, it is necessary to use a generator. Generators tend to emit a large amount of electrical noise, which affects instrument accuracy, and they are prone to power surges that can damage sensitive equipment. As with mechanical instruments, it is not possible to cover all the possible instruments here, but a few common instruments will be discussed.

27.6.2.2.1 Linear Variable Differential Transformers

Linear variable differential transformers (LVDTs) (Figure 27.5) are used to measure displacements. Typical LVDTs will have ranges from 2 to 150 mm (0.1 to 6 in.). The instrument consists of a primary coil, two secondary coils, and a magnetic core. An AC voltage excites the primary coil, which in turn induces voltage in the secondary coils. The amount of voltage in each of the secondary coils depends on the position of the magnetic core. The secondary coils are connected series opposing so only the differential voltage is output. This differential voltage is linear with respect to core position. When using long lead wires, DC is preferred. Many LVDTs contain circuitry so a DC voltage can be input and a DC voltage is output. This is done by converting the input DC voltage to AC and output AC voltage back to DC. Such LVDTs are frequently referred to as DCLVDTs or DCDTs. The main error in an LVDT is linearity error, especially near the ends of the range or in the middle when the LVDT passes the null point where the differential voltage changes sign (Hrinko et al., 1994). Dunncliff (1993) reported that these instruments have no hysteresis, but hysteresis, backlash, and repeatability errors have been found in careful calibration (Hrinko et al., 1994). The LVDT, theoretically, has infinite resolution, but the actual resolution is limited by cable noise and the resolution of the data acquisition system. The instrument responds fast enough to use in any type of testing, including dynamic testing; however, LVDTs have some drift which makes them less than ideal for long-term monitoring.

FIGURE 27.5 Linear variable differential transformer (DC type).

27.6.2.2.2 Wire Potentiometers

Wire potentiometers (Figure 27.6) are also used to measure displacement but have much bigger ranges than the LVDT. Typical ranges for a wire potentiometer are 125 to 900 mm (5 to 30 in.). The potentiometer is a contact that moves along a resistor. The resistance in the circuit changes as the contact moves, and this causes a change in voltage in the circuit. The voltage change is directly proportional to the movement of the contact. In the wire potentiometer, a wire is wound around the spindle of a spring-loaded rotational potentiometer. As the wire is pulled, the potentiometer moves and registers a voltage change proportional to the wire movement. Spring loading keeps the wire taut at all times. As with the LVDT, the wire potentiometer itself has infinite resolution, with the actual resolution limited by the data acquisition system and electrical noise. Wire potentiometers have higher error rates than do LVDTs, but they also have larger ranges, so the error, as a percentage of the range, is about the same as for an LVDT (Hrinko et al., 1994). The main errors in a wire potentiometer are backlash and hysteresis (Hrinko, et al., 1994), which introduce noise in the loading if the wire potentiometer is used as the control instrument in a closed-loop test. The backlash and hysteresis errors also make the instrument unusable for dynamic testing and of marginal use for high-frequency cyclic tests.

27.6.2.2.3 Electrical Resistance Strain Gauges

The electrical resistance consists of several loops of wire bonded to the structure such that the loops are parallel to the direction of strain. Strain in the structure causes strain in the wires which is directly proportional to change in the wire resistance. The change in resistance is read by a wheatstone bridge circuit, which is well known and can be found in most standard physics or electric circuit texts. An excellent discussion of the bridge circuit as it relates to strain gauges can be found in Dunncliff (1993). Resistance gauges come in several types:

- *Bonded foil gauges* consist of a grid of thin metal foil bonded to a plastic backing which in turn is bonded to the structure. These gauges are not particularly useful for concrete. Surface preparation is critical, but it is often difficult to obtain a smooth, clean surface on concrete, especially in the field. The foil gauges are not very robust, so the gauges must be well protected. Even then, though, the gauges will sometimes fail under extreme field conditions or when embedded.

FIGURE 27.6 Wire potentiometer.

- *Weldable gauges* have the wire loops attached to a metal backing which can then be welded to the structure. In concrete structures, these gauges are useful only for attachment to rebar or to metal embedments. As for foil gauges, protection of the gauge is of primary importance.
- *Embedment gauges* are specifically meant to be embedded in concrete. The wire loops are encased in a sheathing that protects the gauge during the casting process.

Levi (unpublished data) found that resistance strain gauges were prone to drift, making them unsuitable for long-term monitoring. He also found that, although modern resistance strain gauges are made to compensate for temperature effects, the strain readings could be influenced by temperature effects in the rest of the system—specifically, the lead wires and bridge completion circuit. Thus, resistance strain gauges are recommended only for short-term or dynamic monitoring, and it is recommended that baseline zero readings be taken before the start of each test. The electrical resistance gauge presents another problem when used with electronic data acquisition, as the gauge requires a completion circuit. It is possible to complete the circuit externally (using three more unstrained strain gauges or three resistors) and then attach the entire circuit to a channel in the data acquisition system, which reads the voltage; however, making and using the external completion bridge can often be difficult and time consuming. To avoid this complication, many data acquisition system manufacturers make special boards with the strain gauge completion bridge already wired in. This allows the strain gauge to be directly attached to the data system. Unfortunately, these boards often have eight, or multiples of eight, channels so some multiple of eight channels must be dedicated to only strain gauges. With the total number of channels in a given system limited, dedicating all these channels to strain gauges may be wasteful if only a few gauges are used. This again illustrates the need for careful planning of the instrumentation system.

27.6.2.2.4 Clip Gauge (Omega Strain Gauge)

The clip gauge (or omega strain gauge) consists of a metal arch attached to two feet such that the resulting structure resembles the capital Greek letter omega (Ω) (Figure 27.7). The arch is instrumented with four resistance strain gauges wired in a full bridge. The feet of the gauge are attached to the structure, usually by gluing metal targets to the structure and then attaching the gauge to the target with bolts. As the targets move with the structure, strain that is directly proportional to the movement of the targets (and the strain in the structure) is induced in the arch. This strain is read by the strain gauges. Use of the arch desensitizes the strain gauges, and the clip gauge can read much larger strains than the strain gauges alone; however, the clip gauge is less accurate than the strain gauge. Clip gauges are easy to install and read and are most useful for measuring fairly large strains (>100 microstrain) over short periods of time under laboratory or otherwise controlled environments. The gauges do exhibit considerable drift and noise and are not suitable for long-term field use.

FIGURE 27.7 Omega or clip gauge.

27.6.2.2.5 Vibrating Wire Strain Gauges

The vibrating wire strain gauge (VWG) is an excellent means of measuring strain in concrete under static or quasi-static conditions. The gauges are accurate to 1 microstrain and are not subject to drift, as are bonded gauges. This means that it is possible to come back to installed VWG years after installation and still obtain accurate strain values; thus, these gauges are well suited to long-term monitoring. VWGs consist of a steel wire, threaded through a tube and attached to two rigid end blocks. These blocks seal the tube but are free to move. The end blocks are either embedded into the concrete or are attached to the concrete surface. When installed, the wire is under an initial tension. An electromagnet is placed around the outside of the tube. On command from the data system, the electromagnet pulses, sweeping various frequencies. One of these frequencies will be the natural frequency of the wire. After sweeping the frequencies, the magnet remains on, and the vibrating wire cuts the magnetic field, creating electrical pulses with the same frequency as the wire vibration. The data system measures these pulses and determines the frequency of vibration. From the frequency, the tension of the wire can be found. This in turn can be used to determine the elongation and the strain in the wire. Because the end blocks are attached to or embedded in the concrete, the change in strain in the wire is the change in strain in the concrete. Although calculation of the strain from the frequency is quite simple, it is also not necessary as most data systems will do the calculations and provide direct strain readings if the gauge calibration factor (supplied by the manufacturer) is input to the data system software.

The main drawback to the VWG is that the process of reading the frequency can take a few seconds, so the gauges are not useful for dynamic situations. The module that excites and reads the wire vibration is expensive, so it is impractical to have a vibrating wire excitation module for each gauge. Normally, multiple gauges are read using a multiplexing unit that allows a single-channel data system to read multiple channels by reading one channel at a time. This allows a large number of VWGs to be read using a single excitation unit. Reading the gauges one at a time does take some time, given the slow response of individual gauges; for example, a 16-channel multiplexing unit reading all 16 gauges may take 15 to 20 seconds. Because the gauges are only used in static or quasi-static tests, this is not a limitation. VWGs also require temperature correction if the gauge is attached to or embedded in something with a coefficient of thermal expansion different from steel. The problem here is that under a temperature change, the wire may expand or contract more than the material to which it is attached, giving a false strain reading. This temperature can be easily corrected with a simple calculation if the calibration temperature (provided by the manufacturer) and the actual temperature are known. Most VWGs have built-in temperature sensors that measure the gauge temperature so the correction can be made. This makes VWGs particularly useful when they are embedded in concrete, as the temperature sensors can measure the heat of hydration and internal curing temperatures. After initial curing, these sensors can measure temperature profiles through the concrete, allowing for calculation of temperature effects in the structure.

In cases where the gauge is used on a steel structure, the wire expands or contracts at approximately the same rate as the structure; thus, the gauge is self-correcting for temperature strains. If the gauge is attached to concrete, the output should be corrected for the difference in the coefficient of thermal expansion between the two materials. Because the coefficient of thermal expansion of concrete varies and is usually not known, the accuracy of any temperature correction is questionable. The coefficient of thermal expansion for concrete is very close to that of steel, so any error in uncorrected data is likely to be small. The vibrating wire gauges are extremely stable and rugged, making them ideal for long-term field measurements.

27.6.2.3 Optical Fiber Strain Gauges

Fiberoptic sensors represent a different method of measuring strain in concrete structures. Unlike electrical sensors, strain is measured by changes in light waves transmitted through the fibers. One such sensor is the Fabry–Perot (Measures, 1995), which consists of two mirrors, separated by a distance (gauge length) set perpendicular to the axis of the fiber. The mirrors can be internal to the fiber or at the ends of two fibers, separated by a gap and joined in a coupler. This device works by sending a coherent (single-wavelength) light beam down the fiber. Some of the light is reflected off of the first mirror, which is only partially reflective. This forms a reference wave. The remaining light passes through the partially reflective mirror, reflects off the second mirror, and passes back through the partially reflective mirror. This second wave is now out of phase with the reference wave because it has traveled a longer distance. When the two waves are combined, an interference pattern results. As the fiber is strained, the distance between the two mirrors changes. This changes the path length of the second wave and therefore the interference pattern. Because the interference fringe pattern is dependent on the wavelength of the light (constant) and the path length, strain can be measured by determining the change in the interference pattern and converting this to a change in path length. A second type of sensor uses a high birefringent optical fiber (Ansari et al., 1996). Here, a circularly polarized light wave is divided into two modes along the principal axes of the fiber. External deformation causes interference of the two modes, and the output has a sinusoidal variation, the period of which is a fringe. The change in length is related to the number of fringes formed. A third type of sensor uses a Bragg grating (Chen and Nawy, 1994; Nawy and Chen, 1996; Measures, 1995). The Bragg grating is imprinted on the fiber lead, making a longitudinal, periodic variation in the refractive index of the fiber core. As light passes through the grating, a portion of the light is reflected, but the reflected light has a spectral shift in wavelength. As the grating is strained, the reflected wavelength changes, and this change in wavelength can be directly related to strain (Figure 27.8). This sensor has the unique capability of pinpointing the strain at precise locations in the structure rather than detecting average strain in a stressed zone. It was originally developed and used in concrete structural research and proved to be effective for online remote-control sensing of the deformation and cracking of structural elements at their critical locations of high stress, using sensors mounted either internally on the reinforcement or externally on the concrete surface.

27.7 Case Studies in Performance Evaluation of Concrete Structures

In surveying the recent literature on performance evaluation, it was found that the great majority of studies concern bridges. This is not to imply that buildings are not evaluated, only that such evaluations are rarely reported. One reason for this may be that bridges are subjected to more severe loading and environmental conditions and are often required by law to have periodic inspections. As a result, performance evaluation of bridge structures may be more frequent. The more probable reason for the lack of published material on building structures, however, may be that buildings tend to be privately held structures whose owners may, for legal reasons, be hesitant to publish information on building deficiencies. Although the material presented here is heavily weighted toward bridge structures, the information is applicable to almost any type of concrete structure.

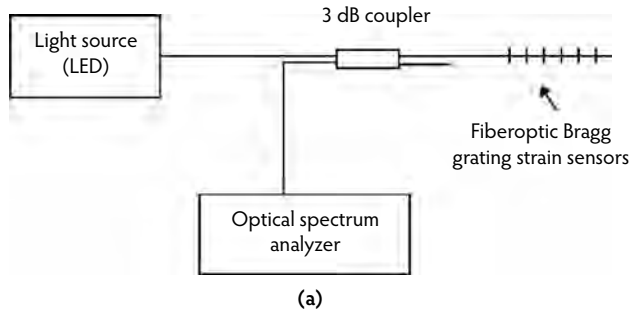

FIGURE 27.8 Fiber optic Bragg grating (FOBG) sensor system. (From Nawy, E.G. and Chen, B., *Fiber optic Sensing the Behavior of Prestressed Prism-Reinforced Continuous Composite Concrete Beams for Bridge Deck Applications*, Transportation Research Board, Washington, D.C., 1997.)

27.7.1 Testing of a Three-Span Slab Bridge

Extensive performance evaluations of a deteriorated, three-span concrete bridge were conducted by Aktan and his team at the University of Cincinnati (Aktan et al., 1992, 1993; Miller et al., 1994). The bridge, shown in Figure 27.9, had extensive deterioration along the shoulders and sides of the slab. The deterioration was so severe that the top mat rebar on the shoulders was completely exposed. The testing of this bridge had three main objectives: (1) to determine how severe deterioration affected the elastic response of the bridge, (2) to determine the effect of deterioration on the load capacity and failure mode of the bridge, and (3) to evaluate the effectiveness of nondestructive testing techniques in bridge evaluation.

The first step in the evaluation of this structure was to determine the cause and extent of the damage. Attempts were made to remove core samples from the shoulder area, but the deterioration was so severe that cores could not be removed intact and came out in layers. Some of these samples were used for material evaluation. Petrographic examination showed that the aggregate had extensively D-cracked. This type of cracking occurs when large pieces of semiporous aggregate are saturated and then permitted to freeze. Some of the aggregate was also reactive, and signs of alkali-silica reaction were found. It is believed that the aggregate cracked and the expansion of the aggregate cracked the surrounding cement paste. This provided a path for water to enter the slab, which then drove the alkali-silica reaction. There were also signs of carbonation, which lowers the pH of the cement paste and creates an environment where corrosion can occur. Chloride testing revealed that the cracked shoulder areas had high chloride contents

FIGURE 27.9 Three-span concrete slab bridge.

from road salt. The chloride, along with the air and water entering the slab through the cracks, caused the steel to corrode, further cracking and damaging the shoulder areas.

It is believed that the deterioration was limited to the shoulder areas because chloride-laden ice and snow would have been pushed to the shoulders by traffic and plows. Here, the snow melted and either ran over the slab edge (no other drainage was provided) or soaked into the porous asphalt layer and was trapped in between the asphalt and the slab. This would have saturated the shoulder area and provided an environment for the deterioration to occur. It is also of interest to note that chloride intrusion and milder signs of corrosion were found over the piers. It is probable that the chlorides entered through flexural cracking. Due to the short span of the bridge (the end span was only 30 ft long), it was found that only one axle would actually be at a critical point in the span as a truck passed (Figure 27.10). This rear tandem axle was duplicated by the use of two loading blocks fitted with hydraulic cylinders. The loading blocks were placed in one lane, as this provided a realistic loading pattern and the researchers felt this would also reveal any effect of nonsymmetrical loading on the slab. Estimates of bridge capacity and performance were obtained by running several finite-element analyses (Shahrooz et al., 1994a).

FIGURE 27.10 Load placement to simulate an HS20-44.

FIGURE 27.11 Instrumentation grid for the slab bridge.

FIGURE 27.12 Final failure of the bridge.

After the finite-element analyses were completed, an extensive instrumentation was instituted (Figure 27.11) for 38 grid points. Two types of instruments were available for measuring deflection: 2-in.-range DCDTs and 10-in.-range wire potentiometers. The points in the loaded span were instrumented with the 10-in.-range wire potentiometers because preliminary finite-element analysis indicated that deflections in excess of 2 in. would be expected. Strains in the reinforcing bars were measured at 11 points on the bottom steel (clustered around the loading blocks) and at 8 points in the top steel (4 over the piers near the loading blocks and 4 at midspan near the loading blocks). Bonded resistance gauges were used in these applications. Concrete strains were measured using DCDTs that were attached between two angles glued 6 in. apart on the slab. After the truck load tests, which measured deflections, the bridge was tested to failure.

Using rock anchors (Figure 27.10), 7-in.-diameter holes were cored at four points in the deck. A 6-in. auger was then passed through the core hole and was used to drill a hole 45 ft into a rock layer beneath the bridge. A cable made of several seven-wire prestressing strands was then grouted into the rock. Two concrete loading blocks were then cast on the bridge deck over the core holes. Four 350-kip-capacity hydraulic cylinders were then placed into holes cast into the loading block. The shafts of cylinders were hollow and the rock anchor cables were passed through the shafts and tied off into button heads.

The loading cylinders were controlled by an electronic controller. This controller was linked to one of the wire potentiometers monitoring deflection below the loading blocks. The bridge was initially loaded to 64 kips (16 kips/cylinder) and then unloaded. Additional load and unload cycles were made to 112 kips and 124 kips. In each case, the bridge remained linear, although some slight hysteresis was observed on unloading. The bridge was reloaded after several days to 700 kips and then unloaded. It showed some nonlinear behavior, and flexural cracking was observed. The bridge failed at a load of 720 kips when it was reloaded the next day. Failure occurred as a circular arc around the loading blocks, resembling a punching-shear type of failure (Figure 27.12).

Subsequent analysis of the data revealed several interesting conclusions for the destructive test (Miller et al., 1994). Initially, the bridge carried the load in a direction parallel to the traffic lanes. When a rotational restraint at the abutment was overcome, the bridge began to carry load perpendicular to the skew. At about 700 kips of total load, the longitudinal reinforcing began to yield, and the load path again shifted to parallel to the traffic lanes. This shifted load back to the damaged corner (as evidenced by a sudden increase in top rebar strain at this location). The load was apparently too much for the damaged shoulder, and it failed in shear with the failure propagating throughout the entire slab. It is also of interest to note that the top steel in the shoulder areas was completely exposed and corroded; however, it was still possible to yield these bars before the failure pulled them out.

A final objective of this test was to determine the effectiveness of multireference modal testing for real structures. As noted in the Section 27.4.3 on modal testing, the test is performed by using an instrumented hammer to create impacts at various locations on the structure and reading the subsequent vibrations with accelerometers. The grid for the impacts was exactly the same as that used for the instrumentation (see Figure 27.11), except that all points shown on the grid were subject to impact, not just those points that were instrumented for the destructive test. A 12-lb sledgehammer, fitted with a load cell, was used for impact. Accelerometers were placed at points B4, C9, D6, D8, H3, I6, J3, L6, L8, M3, and N7 (Figure 27.11). Modal testing successfully located both visible and hidden damage.

The conclusion that can be drawn from the testing program is that concrete-slab bridges are extremely strong, even when damaged. This particular bridge held the equivalent of 22 HS20-44 trucks before failure. Although the damage did not prevent the bridge from safely holding normal traffic loads, it did affect bridge performance, as the final failure probably started in the damaged area.

27.7.2 Truck Load Testing of Damaged Concrete Bridges: Testing for Continuity

In the past, continuous concrete slab bridges were a popular choice for highway spans under 100 ft. Although much of this market has now gone to prestressed concrete, many continuous concrete slab bridges still exist, and many are still being built, especially in rural areas where labor is less expensive and the cost of shipping precast members may be high. The top of the slab bridge tends to deteriorate due to a combination of traffic and road salt. Often the deterioration partially or completely exposes the top reinforcing bars that provide the continuity over the pier supports. When this damage is repaired, deteriorated concrete is removed from the deck and the bars over the piers are further exposed. It is important to determine if the removal of the concrete from around the top bars over the piers could cause a loss of continuity, in effect causing the adjacent spans to behave as simple rather than continuous spans under dead load. In such a case, the dead-load stresses at the midspan of the slabs would increase, decreasing their usefulness.

To test for loss of continuity, three slab bridges were tested before, during, and after repair (Shahrooz et al., 1994b). The bridges were selected so one had minor damage (Bridge 1), one had moderate damage (Bridge 2), and one had severe damage over the piers (Bridge 3). All of the bridges were three-span, continuous-slab bridges. Spans ranged between 20 and 40 ft. The bridges were repaired in the following manner, were tested prior to repair to establish a base, and were retested after repair with truck loading:

- The asphalt layer was removed, along with 1/4 in. of the top of the concrete deck in two of the bridges.
- Three feet of the deteriorated shoulder was removed and replaced.
- All delaminated concrete from the deck was removed, and the deck was patched with microsilica concrete.
- A 1.25-in.-thick microsilica concrete wearing surface was placed on the deck.

To assess continuity, it was necessary to place the loads on the bridges in three load cases: maximum deflection in the middle span, maximum deflection in the end span, and maximum moment over the piers. Test results showed the following:

- For Bridge 1, there was little change in deflection or strains during repair, but an increase in stiffness was found after repair. Due to the low level of damage, this result was expected.
- For Bridge 2, there was little change in stiffness when the damaged shoulder was removed, indicating that the shoulder was so badly damaged that it did not participate in load resistance. After the shoulder was restored, the stiffness of the bridge increased. After the deck was repaired, a further increase in stiffness was noted, showing that the repair was very effective.
- For Bridge 3, there was a large loss of stiffness when the shoulder was removed and a large redistribution of moment. The moment transfer was estimated to increase the dead load positive moment by as much as 50%. It was also found that the stiffness after repair was only slightly greater than the before-repair stiffness, indicating that the repair was only marginally effective.

FIGURE 27.13 Adjacent box-girder bridge.

27.7.3 Testing of Shear-Key Cracking in Adjacent Box-Girder Bridges

The adjacent, precast box-girder bridge is used in over 30 states for short-span bridges (under 100 ft). In this type of bridge, precast box girders are placed side by side to form both the superstructure and the deck of the bridge (Figure 27.13). Often, the boxes are held together by transverse post-tensioning, but the method of post-tensioning varies widely between states. At one extreme, some states use threaded rods, tightened by hand using a turn-of-the-nut method. The rods are often placed only at the quarter points and midspan. At the other extreme, some states use transverse post-tensioning strands that are placed only a few feet apart. Many other intermediate combinations of post-tensioning methods are also used. Load transfer between adjacent boxes is mostly accomplished through the use of a shear key (Figure 27.14). These keys run the length of the box beam and are usually grouted after the transverse post-tensioning is applied. Many states use a nonshrink grout, but this material has often proved unsatisfactory. Some states have switched to magnesium phosphate cements or epoxies.

FIGURE 27.14 Relative displacement between adjacent box girders. (Figure courtesy of A. Hucklebridge, Case Western Reserve University.)

In this case study, deflectometers developed by El-Esnawi (Hucklebridge et al., 1995) were used to determine the extent of cracking and the load transfer in the shear keys. When one end of the deflectometer is displaced relative to the other, the thin element acts like a fixed beam subject to support displacement. This displacement causes moments at the ends of the beam, and the resulting strain from these moments is measured by the strain gauges. Tests conducted in this case study showed that the shear keys had cracked extensively, allowing large relative displacements of the beams (Figure 27.14). This cracking was found even in relatively new or recently repaired bridges; however, measured strains in girders indicated that some load transfer still occurred.

27.7.4 Testing of a High-Rise Building after Collapse

One common reason for testing concrete structures is to ensure structural safety if the materials of construction or the construction techniques are suspected of being faulty. One such case involved the Skyline Plaza Project at Bailey's Crossroads, Virginia (Dixon and Smith, 1980). The Skyline Plaza North Project consisted of an office building, apartments, condominiums, and parking structures. In March 1973, a section of one structure, A-4, collapsed. This collapse occurred shortly after concrete had been placed on the 24th floor of what was to be a 26-story structure. The collapse of this floor started a progressive collapse of the lower floors, resulting in the deaths of 14 workers and injury to 30 more. A study was made of the material properties, slab cracking, and cause of the collapse (Schousboe, 1976), but of interest here is the load testing that was used to determine the safety and salvageability of the uncollapsed part of the structure. The A-4 structure was a flat-plate structure, 76 ft wide and 389 ft long, with irregularly spaced columns. An expansion joint was located 171 ft from the west end of the building. The collapsed area was east of the expansion joint. The investigation of material strengths and slab cracking located 14 areas that were suspect. ACI 318, Chapter 20, was used to determine the test load. The slab self-weight was 77 psf, and an additional 19 psf was calculated as the remaining dead load that would be applied to the structure. The design live load was 40 psf; thus, the total load was $TL = 0.85[1.4(77 + 19) + 1.7(40)] = 172$ psf.

One interesting aspect of this test was the method of load application. The uniform load was applied by flooding the structure. It should be noted that ACI Committee 437 allows for the use of water as a loading method but recommends that the water be confined to tanks or containers. The use of flooding is discouraged, as the water height may vary due to variations in the level of the floor and an uncertain load distribution may be created; however, the flooding method was chosen because a large number of areas had to be tested, and this method could be easily and quickly applied.

Before testing began, all mechanical elements (pipes, ducts, etc.) that might interfere with the test were removed, and holes in slabs for these elements were sealed. A built-up roofing material was placed over the slab to act as waterproofing. This material was not actually attached to the concrete so it could be easily removed after the test to allow post-test inspection of the concrete. Bulkheads were built around the area to be tested. As required by the ACI 318, the acceptance criterion for the slabs was that deflections must be under allowable limits. Due to safety concerns, workers would not be allowed in the building during testing, so remote monitoring of deflections was needed. This was accomplished by using LVDTs mounted on wooden stands that measured the deflection of the slab from underneath.

The first load applied was 3.5 in. of water (approximately 19 psf), which represented the dead load not present on the slab. According to the version of ACI 318 in effect at the time of the test, this load had to be in place for 48 hr before any further testing was done. (A later version, ACI 318-95, did not have this requirement.) At the end of 48 hr, the deflection was measured. The remaining load was then added in three increments (so the total number of increments was 4, as required by the code), with 1 hr elapsing between increments. During the hour wait, deflections were monitored. The total load consisted of 18.5 in. of water: 3.5 in. for the dead load and 15 in. for the live load. This load was left for 24 hr, after which time deflections were measured. The water was then drained so only 3.5 in. of water, representing the increment of dead load, remained. This was left for 24 hr, and deflections were measured again.

Of the original 14 areas tested, 4 did not meet the requirements of ACI 318, which allows for retesting parts of a structure that do not pass a load test, and this was done. After retesting, two of the areas still failed and one showed an increase in slab cracking. The three areas that did not pass the test were strengthened, but the method of strengthening was not reported.

Another interesting part of this evaluation concerned punching-shear tests around the columns. As previously noted, the Skyline Plaza North building was a flat slab. Flat slabs are always at risk for punching-shear failures. Two columns on the tenth floor in an area of the building scheduled to be demolished were subjected to punching-shear tests. The slabs around the columns were shored from the bottom of the tenth floor to the sixth floor. A portion of the slab around the columns was then cut free. (Although the reference does not give the size of the cut-out portions, they appear from diagrams and pictures to be about 30 in. from each face of the column.) Eight holes were cored in the 10th- and 9th-floor slabs, two on each side of the column. A rectangular testing frame made of back-to-back channels was placed over the holes on the 10th floor. Threaded rods were passed between the channels, through the holes, and attached to post-tensioning jacks anchored to the column two floors below the testing frame. The loading sequence was as follows:

- Load all jacks to 3 kips (24 kips total load) and wait 10 minutes.
- Add 5 kips per jack (40 kips total) and wait 10 minutes.
- Add 5 more kips per jack (40 kips total) and wait 10 minutes.
- Add 3 kips per jack (24 kips total).

One slab failed in shear before all the load was applied, at a total load of 120 kips. The other slab was loaded at 1.25 kips/jack/minute until it failed in shear at 128 kips total load. Inclined cracks developed from flexural cracks at approximately 60% of the ultimate load. These cracks propagated upward until only a small compression area remained before failure. The shear loads were less than those anticipated, and shearheads were added at many column locations. As a result of the load-testing program, many parts of the existing structure were strengthened and the building was completed. The authors of the study noted that the completed building now performs well and shows no sign of the collapse.

27.7.5 Testing of Concrete Panels on a Steel Stringer Bridge

In an effort to increase the speed of bridge construction, the Ohio Department of Transportation (ODOT) used precast/prestressed concrete deck panels on a steel stringer bridge. Because this was the first use of that type of panel in Ohio, ODOT had the panels monitored during the construction phase, and they load tested the bridge after construction was complete. Complete details can be found in Dimmerling et al., (2005). The bridge was a 170-ft-long, single-span, steel stringer bridge over I-75 in Findlay, Ohio. The 10-ft by 3-in.-wide deck panels were cast as reinforced elements and then longitudinally post-tensioned prior to shipment (Figure 27.15 and Figure 27.16). The panels were placed with their longitudinal axis perpendicular to traffic. After being shipped to the site, the panels were erected in one evening. Vibrating wire strain gauges were placed in the joints between the panels. After grouting the joints, the panels were laterally post-tensioned together (this post-tensioned the panels in the direction of traffic). Post-tensioning was done before the panels were made composite with the girders. A total of 15 vibrating wire gauges were placed in 5 of 15 joints. The joints chosen were the first joint on each end, the joints at the quarter point of the bridge, and the joint at midspan. Each joint was instrumented with 3 gauges (Figure 27.17 and Figure 27.18). One of reasons for installing the gauges was to determine if the post-tensioning forces were being equally distributed through the joints. There was some concern that, due to friction, the center joints might not receive the complete post-tensioning force. Another concern was how evenly the post-tensioning was applied along the joint.

Table 27.1 shows the strain in the gauges after the post-tensioning was applied. Although there is some variation, the results show a reasonably even distribution of strain after post-tensioning. The post-tensioning would have applied a stress of approximately 400 psi. Assuming a modulus for the grout of 3,000,000 psi, the predicted strain post-tensioning strain would be 137 microstrain, which was consistent

FIGURE 27.15 Plan view of the deck panels.

Average								137									

with the average measured strain of 134 microstrain. When the data from the vibrating wire gauges were analyzed, it was not consistent with the post-tensioning sequence shown on the plans. From the data, the research team was able to reconstruct a post-tensioning sequence, and it was later confirmed that the reconstructed sequence was the one actually used. Grout pockets were left in the panels for the purpose of making the panels composite with the girders. After post-tensioning was complete, studs were welded to the girders in the grout pockets, and the pockets were grouted. Strains measured in the joints in subsequent truck load testing showed that the panels behaved as composite with the steel girders.

28.1 Introduction

Masonry is our oldest permanent construction material. Its has been employed in the construction of castles, forts, majestic cathedrals reaching to the heavens, and simple home shelters for thousands of years. Historically, the design and construction of masonry structures evolved through trial-and-error methods whereby successful designs were repeated and expanded upon. Only during the past century have we begun

* Director of Engineering, National Concrete Masonry Association, Herndon, Virginia; member of codes and standards development committees, including ACI 530/ASCE 5/TMS 402 (*Building Code Requirements for Masonry Structures*) and ACI 530.1/ASCE 6/TMS 602 (*Specification for Masonry Structures*).

to apply in earnest engineering design philosophies and concepts to provide a rational design approach rather than empirical assessment. Despite its long tradition and widespread use, however, masonry remains the least understood of our major construction materials. As with design practices, the physical properties and methods of manufacturing the constituent masonry materials continue to evolve to meet ever-expanding uses and aesthetic demands. The primary purpose of this chapter is to describe and clarify the use of masonry as a construction material in a way that is applicable to modern applications, in addition to, where appropriate, reviewing the historical context from which contemporary masonry design stems. The conventional subjects of constituent masonry materials and construction practices, their governing codes and standards, and the role each component fills in the final masonry assembly are reviewed. As with any construction material, the practice of designing and constructing with masonry materials continuously revises and builds upon previous knowledge. When fitting, design resources and tools will be cited to provide the reader with alternative means of meeting the evolving demands of today's masonry projects.

28.2 Masonry Design and Construction Codes and Standards

By necessity, the long history of masonry construction is only briefly reviewed. Ancient masonry began with sun-dried mud brick, followed by fired clay units, which were used to create stone forts for security and stone cathedrals for spiritual inspiration. With the industrial revolution, many new materials and manufacturing methods were developed that facilitated the use of masonry construction for all types of uses and occupancies. As the use of masonry expanded, so did the need for establishing consistency in material properties, design methods, and construction procedures. Beginning in the early 20th century, the American Society for Testing and Materials (ASTM) published the first standard specifications for masonry units and masonry mortar. These standards supplemented concurrent efforts to codify design and construction practices for masonry structures. Toward the latter half of the 20th century, the use of masonry in the United States was governed primarily by three different model building codes: the Uniform Building Code (UBC), the Standard Building Code (SBC), and the National Building Code (NBC), which in turn drew heavily upon the content of ACI 530/ASCE 5/TMS 402 (*Building Code Requirements for Masonry Structures*) and ACI 530.1/ASCE 6/TMS 602 (*Specification for Masonry Structures*) for masonry design and construction. Today, these three model building codes have merged together under the International Building Code (IBC). Within the context of the discussion presented in this chapter, the requirements of the 2006 IBC, and by reference within the IBC, the collective provisions of the 2005 ACI 530/ASCE 5/TMS 402 *Building Code Requirements for Masonry Structures* (MSJC Code) and 2005 ACI 530.1/ASCE 6/TMS 602 *Specification for Masonry Structures* (MSJC Specification) form the basis for the design and construction requirements reviewed herein. The provisions of ACI 530/ASCE 5/TMS 402 and ACI 530.1/ASCE 6/TMS 602 are developed and maintained by the Masonry Standards Joint Committee (MSJC), a committee jointly sponsored by the American Concrete Institute (ACI), the Structural Engineering Institute of the American Society of Civil Engineers (SEI-ASCE), and The Masonry Society (TMS). These two documents are more commonly (and succinctly) referred to as the MSJC Code and MSJC Specification, respectively. The MSJC Code addresses the minimum structural design requirements for concrete masonry, clay masonry, and aerated autoclaved concrete masonry construction. The MSJC Specification complements the MSJC Code by addressing the minimum requirements for materials, construction, and workmanship. Each document is under continuous review and revision, and a new edition is published every 3 years along with a companion commentary. Additional information on the activities of the MSJC can be found at www.masonrystandards.org.

28.3 Definitions

Many terms have developed over the ages of masonry use that have specific meanings and special connotations as applied to masonry construction. Many such terms and definitions have been formalized by various codes, standards, and industry publications (ACI Committee 530, 2005; ACI Committee

530.1, 2005; ASTM, 2003a,b,c, 2006b; BIA, 2005; NCMA, 2004b). Commonly used terms are provided in the following discussion for ease of reference:

- **Area**—**Mortar bedded area** is the area of the surface of a masonry unit that is in contact with mortar; more commonly refers to a horizontal bed joint but may also apply to a vertical head joint. **Gross area** is the total cross-sectional area of a specified section delineated by the entire out-to-out dimensions of the member. **Net area** is the gross cross-sectional area minus the area of ungrouted cores, notches, cells, and unbedded mortar areas; it is the actual surface area of a cross-section of masonry. **Transformed area** is the equivalent area of one material to a second, based on the ratio of the modulus of elasticity of the first material to the second.
- **Backing**—Backing is a wall or other approved surface to which a veneer assembly is attached.
- **Bond beam**—A bond beam is a horizontal grouted element within an assembly of masonry that contains reinforcement.
- **Cavity**—A cavity is a continuous space, with or without insulation, between wythes of masonry or between masonry and its backup system. A cavity is typically greater than 2 in. (51 mm) in thickness. Conversely, a collar joint is typically less than 2 in. (51 mm) in thickness.
- **Cell**—A cell is a void space within a hollow masonry unit. Also called a *core*.
- **Cleanout**—A cleanout is an opening to the bottom of a grout pour of sufficient size and spacing to allow the removal of debris. Cleanouts are required for high-lift grouting unless it can be shown through the use of a grout demonstration panel that adequate placement and consolidation of grout can be achieved without the use of cleanouts.
- **Collar joint**—The collar joint is a plane between wythes of masonry or between masonry wythe and backup construction, usually filled with mortar or grout. Collar joints are typically less than 2 in. (51 mm) in thickness, whereas a cavity generally refers to a void plane greater than 2 in. (51 mm) in thickness.
- **Column**—For the purposes of masonry design, a column is a reinforced, isolated vertical member whose horizontal dimension measured at right angles to the thickness does not exceed 3 times its thickness and whose height is greater than 4 times its thickness. Columns support loads that act primarily in the direction of the longitudinal axis.
- **Dimensions**—**Actual dimension** is the measured size of a masonry unit or assembly. Nominal dimension is the specified dimension plus an allowance for mortar joints, typically $\frac{3}{8}$ in. (9.5 mm). **Nominal dimensions** are usually stated in whole numbers. Width (thickness) is given first, followed by height and then length. **Specified dimensions** are the dimensions specified for the manufacture or construction of a unit, joint, member, or element. Unless otherwise stated, all calculations are based on specified dimensions. Actual dimensions may vary from specified dimensions by permissible variations defined either by the MSJC Specification or the project documents.
- **Grout lift**—Grout lift is an increment of grout placed at one time within the total grout pour.
- **Grout pour**—Grout pour is the total height of a masonry wall to be grouted prior to the erection of additional masonry, generally in a continuous sequence. A grout pour consists of one or more grout lifts.
- **Joints**—A **bed joint** is the horizontal mortar joint within a masonry assembly. A **head joint** is the vertical mortar joint within a masonry assembly.
- **Masonry unit**—A masonry unit is clay brick, tile, stone, glass block, or concrete block or brick conforming to the requirements specified in the applicable standards. A **hollow masonry unit** is a masonry unit whose net cross-sectional area in every plane parallel to the bearing surface is less than 75% of the gross cross-sectional area in the same plane. A **solid masonry unit** is a masonry unit whose net cross-sectional area in every plane parallel to the bearing surface is 75% or more of the gross cross-sectional area in the same plane.
- **Pier**—A pier is an isolated vertical member whose horizontal dimension measured at right angles to its thickness is not less than 3 times its thickness nor greater than 6 times its thickness and whose height is less than 5 times its length.

- *Prism*—A prism is an assemblage of masonry units and mortar, with or without grout, that is used as a test specimen for determining or verifying the compressive strength of a masonry assemblage.
- *Reinforced masonry*—Reinforced masonry is a form of masonry construction in which reinforcement is embedded in the mortar joints or grouted cells to resist applied loads. For the determination of design strength, the tensile resistance of the masonry is neglected.
- *Unreinforced masonry*—Unreinforced masonry is masonry in which the tensile resistance of the masonry is taken into consideration during design and the resistance of reinforcement, if present, is neglected; also referred to as **plain masonry**.
- *Veneer*—Veneer is a nonstructural facing of brick, concrete, stone, tile, or other approved material attached to a backing for the purpose of ornamentation, protection, or insulation. For design, veneer is assumed to add no strength the structure or element to which it is applied. **Adhered veneer** is a veneer secured and supported through adhesion of an approved bonding material applied over an approved backing. **Anchored veneer** is veneer applied to and supported by approved connectors to an approved backing.
- *Wall*—A wall is a vertical element with a horizontal length-to-thickness ratio greater than 3.
- *Wall tie*—A wall tie is a mechanical metal fastener that connects wythes of masonry to each other or to other materials; also referred to as an **anchor**.
- *Wythe*—A wythe is the portion of a masonry element that is one masonry unit in thickness. Collar joints and cavities are not considered wythes.

28.4 Materials

The quality of materials used in masonry is specified within applicable ASTM standards and the MSJC Specification. When a given material is not covered by specific ASTM or building code requirements, quality shall be based on generally accepted good practice, subject to the approval of the building official. Reclaimed or previously used units shall meet the same applicable requirements for the intended use as for new units of the same material. An overview of masonry materials and their constituent components is provided below. Subsequent sections provide a more detailed review of the primary construction materials, their properties, and methods of evaluation.

- Aggregate
 - ASTM C 144, *Aggregates for Masonry Mortar*
 - ASTM C 404, *Aggregates for Grout*
- Cementitious materials
 - ASTM C 5, *Quicklime*
 - ASTM C 91, *Masonry Cement*
 - ASTM C 150, *Portland Cement*
 - ASTM C 207, *Hydrated Lime*
 - ASTM C 595, *Blended Hydraulic Cements and Slag Cements*
 - ASTM C 618, *Fly Ash and Raw or Calcined Natural Pozzolans*
 - ASTM C 989, *Ground Granulated Blast-Furnace Slag*
 - ASTM C 1157, *Hydraulic Cement*
 - ASTM C 1329, *Mortar Cement*
 - ASTM C 1489, *Lime Putty*
- Masonry units of clay or shale
 - ASTM C 34, *Structural Clay Loadbearing Wall Tile*
 - ASTM C 56, *Structural Clay Nonloadbearing Wall Tile*
 - ASTM C 62, *Solid Clay or Shale Building Brick*
 - ASTM C 126, *Ceramic Glazed Structural Clay Facing Tile and Brick*
 - ASTM C 212, *Structural Clay Facing Tile*

- ASTM C 216, *Solid Clay or Shale Facing Brick*
- ASTM C 652, *Hollow Clay or Shale Brick*
- ASTM C 1088, *Thin Clay or Shale Veneer Brick*
- ANSI A 137.1, *Ceramic Tile*
- Masonry units of concrete
 - ASTM C 55, *Concrete Brick*
 - ASTM C 73, *Calcium Silicate (Sand-Lime) Brick*
 - ASTM C 90, *Loadbearing Concrete Masonry Units*
 - ASTM C 129, *Nonloadbearing Concrete Masonry Units*
 - ASTM C 744, *Prefaced Concrete and Calcium Silicate Units*
 - ASTM C 1386, *Autoclaved Aerated Concrete Masonry Units*
- Masonry units of stone
 - ASTM C 503, *Marble Dimension Stone*
 - ASTM C 568, *Limestone Dimension Stone*
 - ASTM C 615, *Granite Dimension Stone*
 - ASTM C 616, *Quartz-Based Dimension Stone*
 - ASTM C 629, *Slate Dimension Stone*
- Masonry units of glass—Minimum physical properties of glass unit masonry are not covered by ASTM specifications but instead are detailed within *Specification for Masonry Structures* (ACI Committee 530.1, 2005).
- Anchors, ties, and connectors
 - ASTM A 36/A 36M, *Plate and Bent-Bar Anchors*
 - ASTM A 82, *Wire Ties and Anchors*
 - ASTM A 185, *Wire Mesh Ties*
 - ASTM A 307, *Grade A, Anchor Bolts*
 - ASTM A 480 and A 666, *Stainless Steel Plate and Bent-Bar Anchors*
 - ASTM A 480 and A 240, *Stainless Steel Sheet-Metal Anchors and Ties*
 - ASTM A 580, *Stainless Steel Wire Ties and Anchors*
 - ASTM A 1008/A 1008M, *Sheet-Metal Anchors and Ties*
 - Panel anchors for glass unit masonry are not covered by ASTM specifications, but instead are covered within *Specification for Masonry Structures* (ACI Committee 530.1, 2005).
- Mortar
 - ASTM C 270, *Mortar for Unit Masonry*
- Grout
 - ASTM C 476, *Grout for Masonry*
- Reinforcement
 - ASTM A 185, *Plain Welded Wire Fabric*
 - ASTM A 416/A 416M, *Strand Prestressing Tendons*
 - ASTM A 421, *Wire Prestressing Tendons*
 - ASTM A 496, *Deformed Reinforcing Wire*
 - ASTM A 497, *Deformed Welded Wire Fabric*
 - ASTM A 580, *Stainless Steel Joint Reinforcement*
 - ASTM A 615/A 615M, A 706/A 706M, A 767/A 767M, A 775/A 775M, and A 996/A 996M, *Reinforcing Steel*
 - ASTM A 722/A 722M, *Bar Prestressing Tendons*
 - ASTM A 951, *Joint Reinforcement*

28.4.1 Mortar

Mortar has evolved dramatically since its first introduction. The original purpose of mortar was to fill in the spaces between irregular rock or cut stones, but it subsequently evolved into a productivity-

enhancing tool by providing a way to lay masonry units more rapidly and accurately with better stress distribution and alignment. Some of the early exotic mortar mixtures included egg whites, clay, urine, and ox blood. The initial breakthrough in the evolution of masonry mortars was the addition of lime to sand to produce a product that was both workable in the plastic state and durable once cured. Later, Portland cement was added to sand–lime mortars for greater plasticity, higher early strength, and increased bond strength. The result is the cement–lime masonry mortar in use today.

The primary purposes of mortar are to enhance the strength and the homogeneous character of the masonry, to facilitate the workability and laying of units, to improve resistance to moisture penetration, and to provide desired unit alignment. In unreinforced masonry, mortar plays an important structural role by bonding units together and providing flexural tensile resistance. Reinforced masonry, conversely, relies upon the reinforcement to resist tension stresses, thus neglecting any contribution from the mortar–unit bond strength. Although the design of reinforced masonry does not take into account the mortar bond strength, this property is still present in the final assembly and may have to be considered when determining the stiffness and deflection of a masonry member.

28.4.1.1 Mortar Materials

Masonry mortars are a simple mixture of cementitious materials, aggregate, water, and possibly one or more admixtures discreetly combined to achieve a complex set of physical mortar properties. The relative proportions of each of these constituent materials are selected to ensure that both the plastic and hardened mortar properties meet the desired goal. In the plastic state, mortar must have:

- Good workability to facilitate construction and the complete filling of all mortar head and bed joints
- Long board life and water retention to allow the mason sufficient time to spread the mortar before initial set occurs
- Sufficient stiffness to prevent the mortar from squeezing out from the bed joints as subsequent courses of units are laid

Conversely, the hardened mortar must have:

- Good bond strength to the masonry units to prevent the penetration of water or air and, in the case of unreinforced masonry, to provide a minimum level structural bond strength
- Sufficient compressive strength to resist the applied loads
- Long-term durability to meet the exposure conditions in which it will be used

Masonry mortar is specified to meet the requirements of ASTM C 270, *Specification for Mortar for Unit Masonry* (ASTM, 2005d) using either the proportion requirements or property requirements of that standard. When using the proportion requirements of ASTM C 270, the relative quantities of each constituent material are batched to meet the specified mortar type in accordance with Table 28.1. When specifying masonry mortar by property, the physical properties of a laboratory-prepared mortar must meet the properties summarized in Table 28.2. When neither method is specified, the proportion requirements govern.

Despite its long history and worldwide use, mortar remains today one of the less understood and most commonly misapplied construction materials. The largest confusion stems around the minimum compressive strength requirements for field- vs. laboratory-prepared mortars—specifically, the incorrect application of the minimum compressive strength requirements shown in Table 28.2 to mortar prepared in the field. Note 4 of ASTM C 270 includes an extensive discussion detailing the reasons why the mortar properties in Table 28.2 should not be applied to mortar prepared in the field:

The required properties of the mortar in Table [28.2] are for laboratory-prepared mortar mixed with a quantity of water to produce a flow of $110 \pm 5\%$. This quantity of water is not sufficient to produce a mortar with a workable consistency suitable for laying masonry units in the field. Mortar for use in the field must be mixed with the maximum amount of water, consistent with workability,

TABLE 28.1 Masonry Mortar Proportion Requirements

Proportions by Volume (Cementitious Materials)										
Mortar	Type	Portland Cement or Blended Cement	Mortar Cement			Masonry Cement			Hydrated Lime or Lime Putty	Aggregate Ratio (Measured in Damp, Loose Conditions)
			M	S	N	M	S	N		
Cement-lime	M	1	—	—	—	—	—	—	1/4	Over 1/4 to 1/2 Over 1/2 to 1-1/4 Over 1-1/4 to 2-1/2

TABLE 28.2 Property Requirements of Laboratory-Prepared Mortar

Mortar	Type	Average Compressive Strength at 28 Days (min.), psi (MPa)	Water Retention (min.) (%)	Air Content (max.) (%)	Aggregate Ratio (Measured in Damp, Loose Conditions)
Cement-lime	M	2500 (17.2)	75	12	Not less than 2-1/4 and not more than 3-1/2 the sum of the separate volumes of cementitious materials
	S	1800 (12.4)	75	12	
	N	750 (5.2)	75	14 ^a	
	O	350 (2.4)	75	14 ^a	
Mortar cement	M	2500 (17.2)	75	12	
	S	1800 (12.4)	75	12	
	N	750 (5.2)	75	14 ^a	
	O	350 (2.4)	75	14 ^a	
Masonry cement	M	2500 (17.2)	75	18	
	S	1800 (12.4)	75	18	
	N	750 (5.2)	75	20 ^b	
	O	350 (2.4)	75	20 ^b	

^a When structural reinforcement is incorporated in cement-lime or mortar cement mortar, the maximum air content shall be 12%.

^b When structural reinforcement is incorporated in masonry cement mortar, the maximum air content shall be 18%.

in order to provide sufficient water to satisfy the initial rate of absorption (suction) of the masonry units. The properties of laboratory-prepared mortar at a flow of 110 ± 5 , as required by this specification, are intended to approximate the flow and properties of field-prepared mortar after it has been placed in use and the suction of the masonry units has been satisfied. The properties of field-prepared mortar mixed with the greater quantity of water, prior to being placed in contact with the masonry units, will differ from the property requirements in Table [28.2]. Therefore, the property requirements in Table [28.2] cannot be used as requirements for quality control of field-prepared mortar. Test Method C 780 may be used for this purpose.

The question naturally arises that, if the property requirements (including compressive strength) of ASTM C 270 are not to be used to verify compliance with a field-prepared mortar, which properties should be used when, for example, mortar compression cube samples are obtained in the field? While it may defy initial logic, ASTM does not stipulate minimum requirements for the physical properties of field-prepared mortars. In effect, the net resulting compressive strength of a masonry mortar properly batched using quality materials inherently complies with the necessary physical properties.

As stated within ASTM C 270, the default method of complying with the requirements of a given project's specification is through proportioning the constituent mortar materials consistent with the requirements of ASTM C 270 as shown in Table 28.1. When the individual constituent materials (cement, lime, and sand) comply with their respective standards and are batched together in accordance with the proportioning requirements of C 270, the resulting mortar will exhibit the necessary properties for satisfactory, long-term performance. Alternatively, when one of the constituent materials does not comply with the respective standardized requirements (for example, the gradation of a masonry sand, as the properties of sand can have considerable impact on the workability as well as the strength of a mortar) or when a nonstandard material is added to the mortar (such as an admixture used to enhance one or more properties of the mortar), the resulting physical properties of the mortar must be documented. When nonstandardized materials are used within a mortar, each of the constituent materials is batched together in a laboratory in accordance with ASTM C 270. The physical properties of this mortar are then compared to the minimum requirements stipulated by ASTM C 270 as shown in Table 28.2.

If it is desirable to monitor the physical properties of the mortar in the field, then a second batch of mortar is mixed using the same materials, means, and methods to be employed in the field. The evaluated properties of the field mortar are in turn compared to the laboratory mortar. The properties of these two sets of mortar are not expected to be consistent, as discussed in Note 4 of ASTM C 270, above, but this procedure does allow for a direct comparison between the two sets of mortar for future reference. By establishing a correlation between the field and laboratory mortars, samples (often compression cubes) can be obtained during construction and the properties of the sampled mortar compared back to the field mortar prepared in the laboratory. This concept is reviewed in more detail in Section 28.6.

In addition to the base materials of cement, sand, and water, admixtures are also used in masonry mortars to enhance one or more of the characteristics of the material. In accordance with ASTM C 270, admixtures should not be used without the explicit specification and consent of the designer, as some admixtures are not appropriate in some applications or compatible with other admixtures or materials. Admixtures that are commonly used in masonry mortars include coloring pigments, bond strength enhancers, workability enhancers, set retarders or accelerators, water-repellent agents, or any number of other admixtures targeted at altering either the plastic or hardened property of the mortar. Although not required by ASTM C 270, when admixtures are used in masonry mortars it is good practice to ensure that their intended application complies with the requirements of ASTM C 1384, *Standard Specification for Admixtures for Masonry Mortars* (ASTM, 2006a). ASTM C 1384 outlines specific requirements that the physical properties of modified mortar must meet for use in general masonry construction.

Unlike conventional masonry construction, autoclaved aerated concrete (AAC) masonry uses a specially manufactured thin-bed mortar for construction of AAC masonry assemblies. This proprietary mortar is specifically manufactured for use in AAC masonry construction. Because it is preblended, on-site proportioning of thin-bed AAC masonry mortar does not apply. Likewise, testing of thin-bed AAC masonry mortar typically employs third-party manufacturing verification as opposed to jobsite quality control.

28.4.1.2 Selecting a Mortar Type

Masonry mortars are classified by cement—Portland cement, masonry cement, or mortar cement—and further designated by type: Type M, S, N, or O mortar. With one exception, the choice of mortar type is left to the discretion of the designer or specifier. In accordance with the requirements of the MSJC

Code, the single exception applies to the design of elements that are part of the seismic-force-resisting system in Seismic Design Categories D, E, and F, when the mortar must be a Type M or S mortar cement or Portland cement mortar. Because of the vast number of mortar combinations available, the appropriate pairing of a mortar type to a specific application may not always be obvious. As a general rule of thumb, Type N mortars are appropriate in the majority of applications. Exceptions to this guide include high-strength masonry, masonry exposed to severe weathering environments, or where building codes specifically prohibit the use of Type N mortar. In such cases, a Type S or possibly Type M mortar may be warranted or required. The key concept to remember when specifying a mortar type is that overspecifying will likely result in reduced performance and aesthetics; that is, a mortar with an unnecessarily high compressive strength (as indicated by the relative proportion of cement content) in general will not perform as well as its lower strength counterpart. This is due, in part, to the plastic properties of the higher cement content mortar, which tends to be less workable than the same mortar with less cement. This reduction in workability can potentially lead to more voids in the mortar joint, which in turn allows more water to penetrate the assembly; likewise, higher cement content mortars tend to shrink more as they cure. When excessive shrinkage persists, cracking can develop in the mortar joints. In extreme cases, the shrinking mortar may also cause the masonry units to crack as well. Whereas cracking of this nature is typically more aesthetic than structural, it could potentially degrade the strength of a masonry system by allowing water to penetrate the assembly and corrode reinforcement, if present.

In addition to the mortar type designations, three basic cements are used in mortar, each with inherent advantages and limitations:

- *Portland cement–lime mortar* is generally characterized as the mortar with the highest compressive strength, bond strength, and durability but the lowest workability.
- *Masonry cement mortar* has excellent workability but relatively lower compressive strength and bond strength compared to Portland cement–lime mortars.
- *Mortar cement mortar* exhibits good workability analogous to masonry cement mortars, but it is distinguished by retaining the hardened physical properties similar to Portland cement–lime mortars.

Regional practices and preferences, in combination with the local availability of specific masonry cement mortar types, may drive to a large extent the use of each cement type on specific projects. Local suppliers should be consulted when a specific cement type is desired. As reviewed earlier, both the plastic and hardened properties of a masonry mortar must be taken into consideration when specifying a mortar for a particular project. The appendix to ASTM C 270 contains a comprehensive discussion on the selection and use of various masonry mortars for specific applications. Table 28.3 provides a summary list of recommended mortar types for a wide variety of common masonry applications.

28.4.2 Grout

Masonry grout serves several basic functions in masonry construction: (1) it bonds the wythes of multi-wythe construction together into a composite element, (2) it bonds the reinforcement to the masonry so the two materials will act as a homogeneous material in resisting loads, and (3) it increases the masonry volume for bearing, sound abatement, and fire resistance. Despite the widespread belief that masonry grout is concrete, it is not. Grout is produced using the same basic materials as concrete but with a few key differences. Compared to concrete, masonry grout is much more fluid so the grout can flow into and fill all intended cells, cores, and voids within the masonry assembly without segregation. Grout is also intentionally produced with a higher water-to-cement ratio than concrete. The excess water is absorbed by the masonry units as the plastic grout is placed in the masonry assembly. Further, to facilitate its consolidation and minimize the potential for voids to form within the grout, the aggregate size or gradation used in grout production is smaller than that commonly used for concrete. Likewise, grout is not mortar. While both are cementitious materials, grout and mortar exhibit very different physical properties and attributes necessary for their intended application.

TABLE 28.3 Guide for the Selection of Masonry Mortars^a

Location or Application	Building Component	Mortar Type	
		Recommended	Alternative
Exterior, above grade	Loadbearing wall	N	S or M
	Nonloadbearing wall	O ^b	N or S
	Parapet wall	N	S
Exterior, at or below grade	Foundation wall, retaining wall, manholes, sewers, pavements, walks, and patios	S ^c	M or N ^c
Interior	Loadbearing wall	N	S or M
	Nonloadbearing partitions	O	N

^a This table does not provide for many specialized mortar uses, such as chimney, reinforced masonry, restoration, and acid-resistance mortars.

^b Type O mortar is recommended for use where the masonry is unlikely to be frozen when saturated or is unlikely to be subjected to high winds or other significant lateral loads. Type N or S mortar should be used in other cases.

^c Masonry exposed to weather in a normally horizontal surface is extremely vulnerable to weathering. Mortar for such masonry should be selected with due caution.

28.4.2.1 Grout Materials

In accordance with ASTM C 476, *Standard Specification for Grout for Masonry* (ASTM, 2002), the two types of masonry grout are:

- *Fine grout* is characterized by the use of a very fine-grained aggregate similar to that used for masonry mortar.
- *Coarse grout* uses a coarser aggregate with a maximum particle size of just under 0.5 in. (12.7 mm); it is often referred to as *pea gravel*.

The vast majority of grout used today is coarse grout, due in part to its common availability as well as its slightly reduced cost relative to fine grouts. Fine grout is primarily used in clay masonry construction (when grouted) or when cell size or other congestion requires the use of a smaller aggregate to ensure adequate placement and consolidation of the grout.

As with masonry mortar, masonry grout is specified by either proportion or property. When the proportion requirements of ASTM C 476 are used, the individual constituent materials are batched together in accordance with Table 28.4. Although permitted by ASTM C 476, lime is rarely used in masonry grout. Alternatively, any proportion of materials can be used when a minimum grout compressive strength is specified. In accordance with ASTM C 476, the minimum compressive strength of such grouts is 2000 psi (14 MPa) when tested in accordance with ASTM C 1019 (ASTM, 2005f) at a slump of 8 to 11 in. (200 to 280 mm). For ease, as well as having the ability to establish and verify minimum grout compressive strengths in the field, masonry grouts are typically specified by compressive strength instead of proportion.

In addition to conventional masonry grout, self-consolidating grout (SCG) is beginning to see more application throughout the country. One of the primary advantages of SCG is that it is not necessary to mechanically consolidate and reconsolidate after initial water loss, which can translate to significant labor savings. SCG, however, is still in its infancy, and standardized testing, evaluation, and quality control measures are still under development. It is anticipated that the 2008 edition of the MSJC Specification will likely include SCG as an alternative to conventional masonry grout. To ensure that a quality SCG is being used, the following minimum criteria for SCG should be met:

- The visual stability index (VSI), as defined in ASTM C 1611 (ASTM, 2005g), should be less than or equal to 1.
- The slump flow, as determined in accordance with ASTM C 1611, should be 24 to 30 in. (610 to 762 mm).
- Unlike conventional masonry grout, SCG should not be mixed in the field due in part to the difficulty in ensuring consistent and uniform quality.

TABLE 28.4 Masonry Grout Proportion Requirements

Type	Parts by Volume of Portland Cement or Blended Cement	Parts by Volume of Hydrated Lime or Lime Putty	Aggregate (Measured in a Damp, Loose Condition)	
			Fine	Coarse
Fine	1	0–0.1	2.25–3 times the sum of the volumes of the cementitious materials	—
Coarse	1	0–0.1	2.25–3 times the sum of the volumes of the cementitious materials	1–2 times the sum of the volumes of the cementitious materials

- The masonry should be allowed to cure to at least 4 hours prior to placing SCG to minimize blowout potential.
- The minimum compressive strength of SCG should be 2000 psi (13.79 MPa) when tested in accordance with ASTM C 1019.

28.4.3 Concrete Masonry Units

Concrete masonry units come in a nearly infinite array of shapes, sizes, densities, colors, and textures to meet the demands of ever-expanding applications. Due to the wide variation in available products, local availability should be verified prior to specifying a specific product. The most commonly specified and used concrete masonry unit is a hollow, loadbearing concrete masonry unit complying with the requirements of ASTM C 90 (ASTM, 2006c). The types of concrete masonry units permitted by the MSJC Specification include:

- ASTM C 55, *Concrete Brick*
- ASTM C 73, *Calcium Silicate (Sand-Lime) Brick*
- ASTM C 90, *Loadbearing Concrete Masonry Units*
- ASTM C 129, *Nonloadbearing Concrete Masonry Units*
- ASTM C 744, *Prefaced Concrete and Calcium Silicate Units*
- ASTM C 1386, *Autoclaved Aerated Concrete Masonry Units*

Several common concrete masonry unit shapes and sizes are illustrated in Figure 28.1. A comprehensive review of the available options and physical properties of concrete masonry units (see Table 28.5) is provided in *ASTM Specifications for Concrete Masonry Units* (NCMA, 2006a), *Typical Sizes and Shapes of Concrete Masonry Units* (NCMA, 2002b), *Architectural Concrete Masonry Units* (NCMA, 2001a), and the *Concrete Masonry Shapes and Sizes Manual* (NCMA, 2000a).

28.4.4 Clay Masonry Units

The majority of clay masonry units manufactured today are used in nonstructural veneer assemblies; however, many loadbearing, hollow clay tile and brick units options are also available. Hollow brick offers the same advantages as hollow concrete masonry units by allowing the assemblies to be reinforced and grouted. Specialty clay masonry units can also be manufactured, but local availability should be verified prior to specifying. The types of clay masonry units permitted by the MSJC Specification include:

- ASTM C 34, *Structural Clay Loadbearing Wall Tile*
- ASTM C 56, *Structural Clay Nonloadbearing Wall Tile*
- ASTM C 62, *Solid Clay or Shale Building Brick*
- ASTM C 126, *Ceramic Glazed Structural Clay Facing Tile and Brick*
- ASTM C 212, *Structural Clay Facing Tile*
- ASTM C 216, *Solid Clay or Shale Facing Brick*

FIGURE 28.1 Shapes and sizes of concrete masonry units.

TABLE 28.5 Concrete Masonry Unit Physical Properties

Unit Type	Minimum Average Compressive Strength, lb/in. ² (MPa)	Maximum Linear Drying Shrinkage (%)	Maximum Water Absorption, lb/ft ³ (kg/m ³)		
			Weight Classification		
			Lightweight, Less than 105 lb/ft ³ (1680 kg/m ³)	Medium Weight, Less than 105 to 125 lb/ft ³ (1680 to 2000 kg/m ³)	Normal Weight, 125 lb/ft ³ (2000 kg/m ³) or More

^a For use where high strength and resistance to moisture penetration and severe frost action are desired.

^b For general use where moderate strength and resistance to frost action and moisture penetration are required.

^c The compressive strength of C 55 concrete brick and C 73 calcium silicate brick are based on the gross cross-sectional area of the unit.

^d Brick intended for use where exposed to temperatures below freezing in the presence of moisture.

^e Brick intended for use where exposed to temperature below freezing but unlikely to be saturated with water.

^f The concrete masonry units on which the prefaced surface is molded are required to meet the minimum physical properties of C 55, C 73, C 90, or C 129 as specified.

^g Aerated autoclaved concrete masonry units do not limit the maximum water absorption or designate density classes; instead, each unit strength class contains an array of nominal densities ranging from 25 to 50 lb/ft³ (400 to 800 kg/m³).

- ASTM C 652, *Hollow Clay or Shale Brick*
- ASTM C 1088, *Thin Clay or Shale Veneer Brick*
- ANSI A 137.1, *Ceramic Tile*

Several common clay masonry unit shapes and sizes are shown in Figure 28.2.

28.4.5 Reinforcement

To increase the structural resistance to applied loads or to decrease the potential for shrinkage cracks, reinforcement is added to masonry assemblies. Although not immediately apparent, the terms *reinforced* and *unreinforced masonry* refer to the method used to design the masonry structure as opposed to the presence of reinforcing steel; hence, it is possible to have a masonry assembly that contains reinforcement but is designed as unreinforced masonry. In such cases, the masonry is assumed to carry all the applied loads. Conversely, it is not possible to design a masonry structure as reinforced without the inclusion of reinforcement. The majority of reinforcement used in masonry construction falls into one of three categories: (1) conventional mild reinforcement placed in the cells of hollow unit masonry and then grouted, (2) cold-drawn wire reinforcement placed within the horizontal mortar bed joints at the time the units are laid, or (3) prestressing rods or tendons placed within the cells of hollow units, which may then be grouted or ungrouted. A typical reinforced masonry cross-section is shown in Figure 28.3. For design, the MSJC Code limits the specified yield strength of mild reinforcement at 60,000 psi (414 MPa). Material limits for bed joint reinforcement and prestressing reinforcement is limited only by their respective material standards. A comprehensive review of reinforcement options for masonry construction is provided in *Joint Reinforcement for Concrete Masonry* (NCMA, 2005c) and *Steel Reinforcement for Concrete Masonry* (NCMA, 2006b).

FIGURE 28.2 Shapes and sizes of clay masonry units.

28.4.6 Admixtures

Admixtures are available for use in masonry units, mortar, and grout to enhance one or more of the properties or characteristics of the material. In general, admixtures should not be used without the explicit specification and consent of the designer, as some admixtures are not appropriate in some applications or compatible with other admixtures or materials. The most commonly used admixtures are integral water repellents used in the manufacturing of concrete masonry units to increase their resistance to water penetration or to reduce the potential for the formation of efflorescence on the surface of the units. Admixtures are also commonly used in masonry mortars to increase bond strength, enhance workability,

FIGURE 28.3 Reinforced masonry construction. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

retard or accelerate set times, or alter any number of other plastic or hardened mortar property. When admixtures are used in masonry mortars, they should comply with the requirements of ASTM C 1384, *Standard Specification for Admixtures for Masonry Mortars* (ASTM, 2006a). Although ASTM C 270 (ASTM, 2005d) does not currently require compliance with ASTM C 1384, separately specifying compliance to this standard helps to ensure that the admixtures used in the masonry mortar are not detrimental to the overall performance of the material or system.

28.5 Construction

The limitless combinations of masonry unit shapes, sizes, and physical properties; mortar types and mortar joint profiles; grout placement options; reinforcement details and schedules; and structural configurations permit boundless versatility in masonry construction, but this design flexibility can also

result in confusion during implementation, particularly among design personnel not familiar with the details of masonry construction. Although some construction practices are mandated by the MSJC Specification, many are simply standards of care that have developed over the long history of masonry construction. Where not covered by national codes or standards, regional differences in construction practices and preferences do surface and should be accounted for during the initial design phase.

28.5.1 Modular Layout

Masonry structures can be constructed using virtually any layout dimension. For maximum construction efficiency and economy, however, masonry elements should be designed and constructed using a modular layout of the structure and its openings. Modular coordination is the practice of laying out and dimensioning structures and elements to standard lengths and heights to accommodate modular-sized building materials. On occasion, modular coordination issues are not considered during the design phase. As a result, jobsite decisions must be made—often in haste and at a cost. When a project does require a non-modular layout, further design and construction considerations must be addressed, including:

- *Placement of vertical reinforcement*—In construction containing vertical reinforcing steel, the laying of units in other than running (half) bond or stack bond interrupts the vertical alignment of individual confined cells. As a result, the placement of reinforcement and adequate consolidation of grout becomes difficult, if not impossible.
- *Interruption of bond pattern*—In addition to the aesthetic impact that a change in the bond pattern can create, building codes often contain different design assumptions for masonry constructed in running bond vs. other bond patterns. Walls incorporating more than a single bond pattern may present a unique design situation.
- *Locating control joints*—In running bond construction, the incorporation of control joints can be accomplished using only full- and half-size units. Similarly, stack bond construction only requires full-size units when control joints are properly spaced and detailed. With other bond patterns, however, the cutting of units may become necessary if specially dimensioned units are not used or are not available.

Standard concrete masonry modules are typically 8 in. (203 mm) vertically and horizontally, but may also include 4-in. (102-mm) modules for some applications. These modules provide overall design flexibility and coordination with other building products such as windows, doors, and other similar elements. The impact of non-modular openings is illustrated in Figure 28.4.

In addition to wall elevations, sections, and openings, the overall plan dimensions of a structure must also be considered, especially when using units having nominal widths other than 8 in. (203 mm). Consider, for example, a square building with outside nominal dimensions of 360 in. (30 feet) (9144 mm), which is evenly divisible by 8 and therefore modular. Using 8-in. (203-mm) units and a running bond pattern, the walls can be constructed without cutting the units. If units 12-in. (305-mm) wide were used instead of the 8-in. (203-mm) units, however, at least one block must be cut shorter to accommodate the increased thickness of the end unit oriented perpendicular to the length of the wall, as shown in Figure 28.5. To minimize the need for cutting units, building plan dimensions should be evenly divisible by 8 in. (203 mm) plus the nominal thickness of the units used in construction. As an alternative to cutting, specially configured corner units may be available in some regions for turning corners.

28.5.1.1 Masonry Bond Patterns

The term *bond* can generally refer to two different topics within masonry design and construction; the adhesive or mechanical interlock between mortar and units or the arrangement of units to achieve a desired pattern. This section addresses the latter. Figure 28.6 illustrates a few of the many different masonry bond pattern options available. Masonry bond patterns can be created by varying the unit heights or lengths, varying the length the units overlap from one course to the next, varying the orientation of the units, or by using units of different configurations in the same wall. Implementing one or

Not recommended construction:

Utilizing nonmodular layouts or openings results in unnecessary cutting of the masonry units (shown here as shaded). The end product is more difficult to construct, produces more waste, and is more costly compared to a similar structure employing a modular layout. Additionally, placing and consolidating grout in the reduced-size cores of the saw-cut units may prove difficult.

 = Nonstandard or field-cut units

In this example, it is obvious the aesthetic impact that nonmodular layouts have on the final appearance of a structure. Not so obvious is the additional cost of construction. To further illustrate this concept, consider the following comparison of the modular and nonmodular layouts shown here:

Total area of nonmodular layout = 122.4 ft² (11.38 m²)

Total area of modular layout = 126.7 ft² (11.77 m²)

Number of units used in nonmodular layout = 112

Number of units used in modular layout = 106

Recommended construction:

The wall elevation shown here reduces cutting of units by utilizing modular openings and opening locations. (That is, each dimension shown is evenly divisible by 8 inches [203 mm].) Through the coordination of opening sizes and locations, the cells of hollow masonry units align (which facilitates the placement of vertical reinforcement and consolidation of grout), labor time is reduced, and materials are not wasted.

Ç

FIGURE 28.4 Modular masonry layout. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

more of these alternatives can subtly or dramatically alter the appearance of a finished masonry assembly. The aesthetic impact created by a specific bond pattern can be even more dramatic when combined with units of varying color, texture, or material.

The evolution of various masonry bond patterns has continued for centuries. As such, regional differences in terminology or construction practices have developed. The designer should be cautioned against specifying unique or complex bond patterns without thoroughly communicating the intent to the mason contractor. When specifying a unique bond pattern, elevation drawings for a particular project should clearly illustrate the intended final appearance of the structure. Also, when specifying a bond pattern that incorporates unique or nonstandard unit sizes, the availability of such units should first be verified with local manufacturers.

FIGURE 28.5 Nonmodular layout of masonry corners. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

The most common bond pattern in masonry construction is running bond, typically where vertical head joints of successive courses are offset by one-half the unit length. Building code design provisions (ACI Committee 530, 2005) are based primarily on structural research of wall panels laid in running bond construction. As such, the MSJC Specification (ACI Committee 530.1, 2005) requires the use of running bond unless otherwise specified. When a different bond pattern is used, the designer should consider its impact on the performance and structural capacity of the masonry element.

28.5.1.2 Metric Coordination

One additional consideration for some projects is the incorporation of standard-sized (inch-pound) units in a metric project. Similar to inch-pound units, masonry units produced to metric dimensions are 10 mm (0.39 in.) less than the nominal dimensions to accommodate the thickness of the mortar joints. Thus, the nominal metric equivalent of an $8 \times 8 \times 16$ -in. unit is $200 \times 200 \times 400$ mm ($190 \times 190 \times 390$ mm specified dimensions for a 10-mm mortar joint thickness). Because inch-pound dimensioned concrete masonry units are approximately 2% larger than hard metric units, complications can arise if they are incorporated into a structure designed according to the 100-mm (3.9-in.) metric module or *vice versa*. Additional recommendations are provided in *Metric Design Guidelines for Concrete Masonry Construction* (NCMA, 2000b) for the incorporation of soft metric units (standard inch-pound units) into a hard metric design project.

28.5.2 Mortar

Although mortar comprises only approximately 7% of the wall surface in typical concrete masonry construction, it can have a significant impact on the aesthetics and performance of the constructed masonry assembly. Head and bed joints are typically $3/8$ in. (9.5 mm) thick, except for the initial bed joint at foundations, which can range from $1/4$ to $3/4$ in. (6.4 to 19 mm) to accommodate surface irregularities in the foundation. Mortar should extend fully across the thickness of the face shells of hollow units so both head and bed joints will be completely filled. Solid units are required to be fully bedded in mortar. To perform properly, all voids in mortar joints (except weep holes) should be filled with mortar. Although it is important to provide sufficient mortar to properly bed masonry units, mortar should not extend excessively into drainage cavities or into cores to be grouted. For grouted masonry,

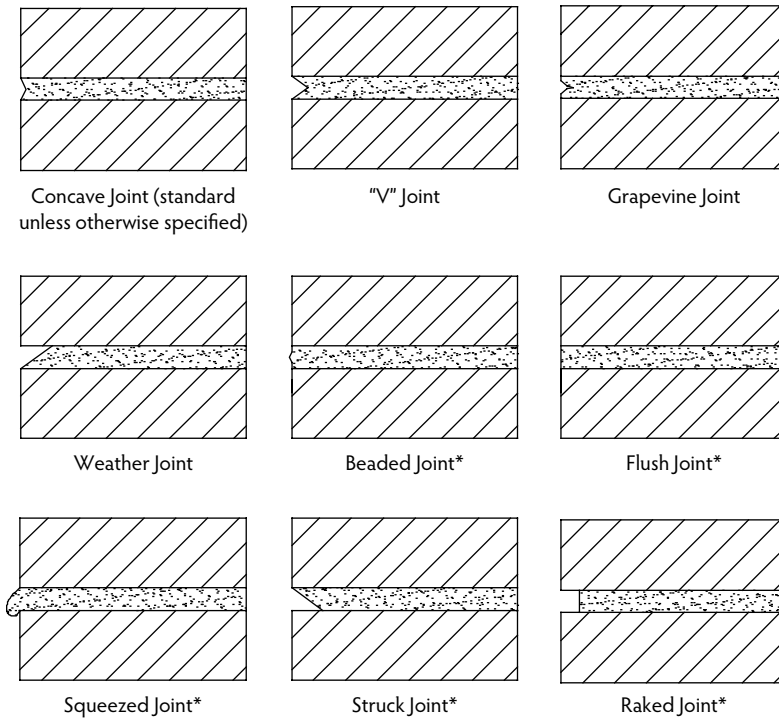

FIGURE 28.6 Masonry bond patterns. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

mortar protruding more than 1/2 in. (13 mm) into the cells or cavities to be grouted is not permitted (ACI Committee 530.1, 2005). Mortar joints should be tooled when thumbprint hard. For walls exposed to weather, concave or V-shaped joints improve water penetration resistance by directing water away from the wall surface and by compacting the mortar against the masonry unit to seal the joint. Tooling mortar joints also helps to seal the outer surface of the joint. Raked, flush, struck, beaded, or extruded joints are not recommended for exterior construction as they generally do not provide as tight a seal and may create ledges that can hold water near the wall face. For walls not exposed to weather, the selection of the joint profile can be based on aesthetics rather than functionality. Several different mortar joint profiles are illustrated in Figure 28.7.

28.5.3 Grout Placement

The versatility of grout allows it to be either mixed in the field or transported to the jobsite in a ready-mixed condition. Once mixed, grout is placed by hand or, on larger projects, is placed by pump or other mechanical delivery method. Over time, an empirical set of guidelines has been established for the

*Potentially poor weathering joints, not recommended for exterior construction.

FIGURE 28.7 Mortar joint profiles. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

successful placement and consolidation of masonry grout based on the size of opening to be grouted and the type of grout used. These practices for the placement of grout have been standardized by the MSJC Specification as detailed in Table 28.6.

At the time of placement, grout is required to have a slump of 8 to 11 in. (203 to 279 mm) for grout lifts up to 5 ft (1.52 m). For grout lifts between 5 and 12.67 ft (1.52 and 3.86 m), the grout slump is limited to 10 to 11 in. (254 to 279 mm). The high water content of masonry grout is necessary to ensure that the cells and cavities intended to be grouted are completely filled and void free while maintaining a sufficient amount of water in the plastic grout mix for hydration of the cement following the absorption of the free water of the grout by the masonry units. AAC masonry assemblies, however, unlike clay and concrete masonry assemblies, are required to be thoroughly wetted prior to placement of the grout due to the relatively high absorptive nature of AAC masonry units. Because of the relatively high water content of masonry grout, care is required when handling, placing, and consolidating grout, as too much water or excessive consolidation can result in segregation and voids in the final product.

In addition to the grout pour height limits of Table 28.6, grout must be placed in lifts not exceeding 5 ft (1.52 m), regardless of the total grout pour height. The MSJC Specification offers an exception to this requirement in that it allows grout lifts up to 12.67 ft (3.86 m) when the following conditions are met:

- The masonry has cured for at least 4 hours.
- The grout slump is maintained between 10 and 11 in. (254 and 279 mm).
- No intermediate reinforced bond beams are placed between the top and bottom of the pour height.

If any of these conditions is not met, the maximum grout lift height defaults to 5 ft (1.52 m).

After each grout lift is placed, the grout is consolidated by mechanical vibration and then reconsolidated a short time later after the excess water in the grout is absorbed by the masonry units. Consolidation of

TABLE 28.6 Grout Placement Requirements

Grout Type	Maximum Grout Pour Height, ft (m)	Minimum Width of Grout Space, ^{a,b} in. (mm)	Minimum Grout Space Dimensions for Grouting Cells of Hollow Units, ^{b-d} in. × in. (mm × mm)
Fine	1 (0.30)	0.75 (19)	1.5 × 2 (38 × 51)
Fine	5 (1.52)	2 (51)	2 × 3 (51 × 76)
Fine	12 (3.66)	2.5 (64)	2.5 × 3 (64 × 76)
Fine	24 (7.32)	3 (76)	3 × 3 (76 × 76)
Coarse	1 (0.30)	1.5 (38)	1.5 × 3 (38 × 76)
Coarse	5 (1.52)	2 (51)	2.5 × 3 (64 × 76)
Coarse	12 (3.66)	2.5 (64)	3 × 3 (76 × 76)
Coarse	24 (7.32)	3 (76)	3 × 4 (76 × 102)

^a For grouting between masonry wythes.

^b Grout space dimension is the clear dimension between any masonry protrusion and shall be increased by the diameters of the horizontal bars within the cross-section of the grout space.

^c Area of vertical reinforcement shall not exceed 6% of the area of the grout space.

^d Minimum grout space dimension for AAC masonry units shall be 3 × 3 in. (76 × 76 mm) or a 3-in. (76-mm)-diameter cell.

the grout by puddling using either the vertical reinforcing bars or by other means is permitted only when the total grout pour height is 12 in. (305 mm) or less (ACI Committee 530.1, 2005). When the grout pour height exceeds 5 ft (1.52 m), cleanouts are required at the base of the cells or cavities to be grouted to remove mortar droppings and other debris as shown in Figure 28.8. For solid grouted masonry construction, the

FIGURE 28.8 Cleanouts. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

maximum spacing between cleanouts is 32 in. (813 mm). Cleanouts are required to be of sufficient size to permit the removal of mortar droppings but not less than 3 in. (76 mm) in any dimension. To preclude the need for constructing and subsequently sealing cleanouts, some masons opt to employ low-lift grouting techniques whereby no more than 5 ft (1.52 m) of masonry is constructed at one time before the grout is placed. When the grout has been placed, construction of the masonry assembly and placement of the grout continues in increments not exceeding 5 ft (1.52 m) until the full assembly height is achieved. Alternatively, the entire height of the masonry assembly permitted by Table 28.6 is constructed in a single stage prior to grout placement. This construction technique is generally referred to as *high-lift grouting*. A detailed review of grouting of masonry is provided in *Grouting Concrete Masonry Walls* (NCMA, 2005b).

28.5.3.1 Alternative Grouting Techniques

Adherence to the above requirements for the placement of grout ensures that the masonry assembly will be free of unintended grout voids and that the structure will perform as designed. In some circumstances, however, deviating from these practices may be warranted or alternative grout placement techniques may be desired. Such instances may include higher grout lifts or pours, smaller cavity widths or cells sizes, unique consolidation methods, or altered grout slumps or materials. In recognition of the need to deviate from these standardized grout placement procedures, the MSJC Code and MSJC Specification include an option for the construction of a grout demonstration panel to verify that the alternative grout materials or grouting techniques results in the adequate placement and consolidation of the grout. Although the MSJC is silent on recommended procedures for ensuring the successful placement and consolidation of the grout, common verification methods include both nondestructive evaluation, such as infrared photography, and destructive evaluation, such as the removal of samples from the masonry assembly for testing or visual inspection. If the alternative grouting techniques are shown to be successful, those procedures then become the minimum acceptable standard of care for the project. Although not commonly employed, it is permitted to use a portion of the actual construction as the grout demonstration panel, recognizing that an unsuccessful grout placement alternative may require the removal of the affected portion of construction.

28.5.4 Bracing of Masonry

In accordance with the MSJC Specification, the need to provide, design, and install bracing to ensure the stability of the masonry assembly during construction is left to the mason contractor to implement unless unique construction loads are expected, in which case the designer may opt to provide bracing requirements. Placing this responsibility on the mason contractor recognizes both the need to remain flexible in the field when constructing masonry as well as the variable construction schedule and sequence that may not be anticipated by the designer, thus inhibiting the effective implementation of a bracing strategy. To aid the mason contractor in providing a safe and economical bracing procedure, the MSJC Specification recommends following the guidelines established in *Standard Practice for Bracing Masonry Walls Under Construction* (NCMA, 2001b). This guide contains a series of bracing triggers based on wall age, thickness, height, and weight over a range of wind speeds. As an alternative to providing bracing, which may be impractical in certain instances and loading conditions, procedures are also outlined whereby the assembly and the area around it are evacuated at prescribed wind speeds. Under this alternative, the assembly is considered sacrificial, and the protection of life is the primary concern.

28.5.5 Environmental Construction Factors

In some regions, construction of masonry structures during cold, hot, or wet weather is unavoidable. The ability to continue masonry construction in adverse weather conditions requires consideration of how environmental conditions may affect the quality of the finished masonry. When cold or hot weather is anticipated, the MSJC Specification includes a set of required construction procedures to ensure that the masonry work is not adversely affected. One of the prerequisites of successful all-weather construction is an advance knowledge of local weather conditions. Work stoppage may be justified for a short period

TABLE 28.7 Cold-Weather Construction

Ambient Temperature	Construction Requirements
32 to 40°F (0 to 4.4°C)	Do not lay units having a temperature below 20°F (−6.7°C). Remove visible ice and snow from units, foundation, and masonry to receive new construction. Heat foundation and existing masonry construction to receive new units above freezing. Heat sand or mixing water to produce a mortar temperature of 40–120°F (4.4–48.9°C) at the time of mixing. Heat grout materials to a minimum of 32°F (0°C). Do not heat mixing water or aggregates above 140°F (60°C).
25 to 32°F (−3.9 to 0°C)	In addition to above, maintain mortar temperature above freezing until used. Heat materials for grout to produce a temperature from 70–120°F (21.1–48.9°C). Maintain grout temperature above 70°F (21.1°C) when placed. Heat AAC unit to a minimum temperature of 40°F (4.4°C) before applying mortar.
20 to 25°F (−6.7 to −3.9°C)	In addition to above, heat masonry under construction to 40°F (4.4°C) and use wind breaks or enclosures when the wind velocity exceeds 15 mph (24 kph).
20°F (−6.7°C) and below	In addition to above, provide an enclosure and auxiliary heat to maintain air temperature above 32°F (0°C) within the enclosure.
Mean/Minimum Daily Temperature for UngROUTED/Grouted Masonry	Protection Requirements
25 to 40°F (−3.9 to 4.4°C)	Cover newly constructed masonry with weather-resistive membrane for 24 hours after completion.
20 to 25°F (−6.7 to −3.9°C)	Extend above time period to 48 hours for grouted masonry, unless the only cement in the grout is Type III Portland cement.
20°F (−6.7°C) and below	In addition to above, maintain newly construction masonry temperature above 32°F (0°C) for at least 24 hours after completion. Extend to 48 hours for grouted masonry unless the only cement in the grout is Type III Portland cement.

if very cold, very hot, or extreme weather is anticipated. Several sources for this type of information are available, including the National Weather Service of the U.S. Environmental Science Services Administration (ESSA), which can be accessed at their website (<http://www.ncdc.noaa.gov>). In the following discussion, *ambient temperature* refers to the surrounding jobsite temperature when construction is in progress. The *mean daily temperature* is the average of the hourly temperatures forecast by the local weather bureau over a 24-hour period following the onset of construction. Likewise, the *minimum daily temperature* is the lowest temperature forecast over this 24-hour period. Temperatures between 40 and 90°F (4.4 and 32.2°C) are considered normal temperatures for masonry construction and therefore do not require special procedures or protection protocols.

28.5.5.1 Cold-Weather Construction

Hydration and strength development in mortar and grout generally occur at temperatures above 40°F (4.4°C) and only when sufficient water is available. Masonry construction may proceed, however, when temperatures are below 40°F (4.4°C), provided cold-weather construction and protection requirements of the MSJC Specification are followed as summarized in Table 28.7. The initial water content of mortar can be a significant contributing factor to the resulting properties and performance of mortar, affecting workability, bond, compressive strength, and susceptibility to freezing. Research has demonstrated a detrimental expansion effect on the cement–aggregate matrix when fresh mortars with water contents in excess of 8% mortar are frozen (Korhonen et al., 1997). This disruptive effect increases as the water content increases; therefore, mortar should not be allowed to freeze until the mortar water content is reduced from the initial range of 11 to 16% to a value below 6%. Dry masonry units have a demonstrated capacity to achieve this moisture reduction in a relatively short time. It is for this reason that the MSJC

TABLE 28.8 Hot-Weather Construction

Ambient Temperature	Construction Requirements
Above 100°F (37.8°C), or above 90°F (32.2°C) with a wind speed greater than 8 mph (12.9 kph)	Maintain sand piles in a damp, loose condition. Maintain mortar and grout temperature below 120°F (48.9°C). Flush tools and equipment with cool water before they come into contact with mortar. Maintain mortar consistency by retempering with cool water. Use mortar within 2 hours of initial mixing. Spread thin-bed mortar for AAC masonry no more than 4 ft (1.22 m) at a time, and place AAC masonry units within 1 minute after placing thin-bed mortar.
Above 115°F (46.1°C), or above 105°F (40.6°C) with a wind speed greater than 8 mph (12.9 kph)	In addition to above, shade materials and mixing equipment from direct sunlight. Use cool mixing water for mortar and grout. Ice is permitted in mixing water as long as it is completely melted when added to the other mortar or grout materials.
Mean Daily Temperature	Protection Requirements
Above 100°F (37.8°C), or above 90°F (32.2°C) with a wind speed greater than 8 mph (12.9 kph)	Fog spray newly constructed masonry until damp, at least 3 times per day until the masonry is 3 days old.

Specification requires protection from freezing of mortar for only the first 24 hours. Like mortar, the freezing of a plastic grout can reduce bond and strength development, reducing overall performance of the structure. During cold weather, however, more attention must be directed toward the protection of grout because of the higher water content and resulting expansion that can occur from freezing of that water. Grouted masonry, therefore, generally must be protected for longer periods to allow the water content to be dissipated and the grout to cure.

28.5.5.2 Hot-Weather Construction

High temperatures, solar radiation, and ambient relative humidity influence the absorption characteristics of the masonry units and the setting time and drying rate for mortar. When mortar or grout gets too hot or when mortar or grout is placed in contact with excessively hot masonry units, they may lose water so rapidly that the cement does not fully hydrate. Early surface drying of the mortar results in decreased bond strength and less durable mortar. The hot-weather construction procedures of the MSJC Specification as summarized in Table 28.8 involve keeping masonry materials as cool as possible and preventing excessive water loss.

28.5.5.3 Wet-Weather Construction

When the moisture content of a masonry unit is elevated to excessive levels due to wetting by rain or other sources, several deleterious consequences can result, including decreased mason productivity, decreased mortar–unit bond strength, and, in the case of concrete masonry, increased shrinkage potential and possible cracking. Although reinforced masonry construction does not rely on mortar–unit bond for structural capacity, this is a design consideration with unreinforced masonry. As a means of determining if a concrete masonry unit has acceptable moisture content at the time of installation, the following industry guidance is recommended (NCMA, 2002a). This simple field procedure can quickly ascertain whether a concrete masonry unit has acceptable moisture content at the time of installation.

A concrete masonry unit for which 50% or more of the surface area is observed to be wet is considered to have an unacceptable moisture content for placement. If less than 50% of the surface area is wet, the unit is acceptable for placement. Damp surfaces are not considered wet surfaces. For this application, a surface would be considered damp if some moisture is observed, but the surface darkens when additional free water is applied. Conversely, a surface would be considered wet if moisture is observed and the surface does not darken when free water is applied. These limitations on maximum permissible moisture content are not intended to apply to intermittent masonry units that are wet cut as needed for special fit.

The relative moisture content of clay masonry units at the time of installation is evaluated through the initial rate of absorption (IRA), which is a measure of how much water the brick absorbs during the first 60 seconds after contact with fresh mortar. The value of the initial rate of absorption can influence the bond that can develop between the unit and mortar. When the IRA exceeds 30 g/min/30 in. (30 g/min/194 cm²), the unit may be too dry and a solid, watertight joint may not be achieved (ACI Committee 530.1, 2005). High IRA brick should be wetted 3 to 24 hr prior to laying to reduce the suction and to allow the surface of the brick to dry. Conversely, very low IRA brick should be covered and kept dry on the jobsite prior to use. Guidelines do not exist for the moisture content of AAC masonry units at the time of installation, due in part to the unique properties of the thin-bed mortar used in AAC masonry construction. AAC masonry is required to be thoroughly wetted, however, prior to the placement of grout.

28.5.6 Cleaning

During construction, it is often difficult to prevent the accumulation of mortar and grout smears on the surface of the masonry assembly. Recognizing this, many masonry project specifications include provisions for cleaning the completed masonry assembly following construction. Several commercially available products are available for cleaning the surface of newly constructed masonry. Cleaning products and procedures should be selected with due care, as overly aggressive techniques can damage the masonry units or mortar. Cleaning should begin in a small, nondescript location of the structure to verify that the proposed procedures and solutions are not detrimental to the masonry substrate. For years, acids were used to clean masonry following construction, occasionally with detrimental results. Today, acids and other aggressive chemical are only recommended as a last option for cleaning, and even then should be used with caution. Before applying an acid, the masonry should be thoroughly wetted to prevent the acid from being absorbed into the masonry substrate. Failure to do so can cause acid burn when the cementitious paste between the aggregates is washed away, thus altering the appearance of the surface finish.

28.5.7 Construction Tolerances and Workmanship

Although the manufacturing of masonry units has evolved considerably over the past 100 years, the construction of masonry assemblies remains today a hand-crafted art that has been practiced over centuries. The charm and beauty inherent to masonry construction are its primary aesthetic draws. To ensure that the masonry performs as intended, the MSJC Specification has established tolerance and placement requirements. Workmanship, however, can be a much more subjective value to quantify. For this reason, when aesthetics are a primary concern, the construction of a sample panel is recommended for all projects.

28.5.7.1 Construction Sample Panels

When masonry construction is governed by either quality assurance Level B (see Table 28.10) or Level C (see Table 28.11) as required by the MSJC Specification, a sample panel measuring a minimum of 4 × 4 ft (1.22 × 1.22 m) is required to be constructed, although sample panels can also be used on projects incorporating unique or complicated details or procedures. The purpose of a masonry sample panel is to help ensure that the final envisioned product is directly communicated to all affected parties, particularly in the case of aesthetics and minimum quality of workmanship, which can be difficult to stipulate in contract documents. The sample panel should incorporate all possible products, materials, and procedures specified to be part of the final construction, including the full range of masonry unit color and texture; mortar color and joint profile; flashing details; tie, anchor, and reinforcement placement; cleaning procedures; and coating application, as applicable. The sample panel should be retained on the project site until all masonry work has received final acceptance. If appropriate and acceptable to all parties, a portion of the masonry structure can be used as the sample panel for the project.

28.5.7.2 Construction Tolerances

Virtually all construction materials are manufactured to a specified tolerance; likewise, nearly all structures incorporating such building components are required to be constructed to a specified tolerance. Masonry structures and the materials used in their construction are no different. Because masonry is often used as an exposed construction material, it can be subjected to tighter tolerances than typically associated with other structural systems that are normally hidden when construction is complete. Unless otherwise specified in the contract documents, the tolerances for the placement of masonry elements are outlined in the MSJC Specification. Although the intent of the construction and placement tolerances contained within the MSJC Specification is to safeguard structural performance and not achieve any aesthetic criterion, the stipulated values are often regarded as more than adequate for common aesthetic purposes. Tighter tolerances may be required in the project documents to ensure that the final overall appearance of the masonry is acceptable. It should be cautioned, however, that using more stringent construction tolerances could significantly complicate the job and increase the cost of construction. Maintaining tight construction tolerances may be aesthetically desirable, but it must be recognized that factors such as the condition of previous construction and modular coordination of the project may require the mason to vary the masonry construction slightly from the intended plans or specifications. The details of this section outline the tolerance requirements contained within the MSJC Specification for mortar joints, alignment, location of elements, and placement of reinforcement. Further information on construction tolerances can be found in *Testing and Inspection of Concrete Masonry Construction* (NCMA, 2006c).

28.5.7.2.1 Mortar Joint Tolerances

Although primarily an aesthetic issue, significant variations in mortar joint thicknesses can result in poor structural performance. The following tolerances imposed by the MSJC Specification are intended, in part, to ensure structural performance is not compromised. These tolerances are illustrated in Figure 28.9. Mortar bed joints, typically 3/8 in. (9.5 mm) thick for most masonry construction, are permitted to vary by $\pm 1/8$ in. (3.2 mm) in thickness. The exception to this is with the initial bed joint between the top of the footing and the first course of masonry, which may vary in thickness from 1/4 to 3/4 in. (6.4 to 19 mm) to accommodate variations in the top of the footing. Head joint thickness may vary by $-1/4$ in. (6.4 mm) to $+3/8$ in. (9.5 mm); thus, for a specified joint thickness of 3/8 in. (9.5 mm), the head joint thickness may vary from a minimum thickness of 1/8 in. (3.2 mm) to a maximum thickness of 3/4 in. (19 mm). Although bed joints should be constructed level, they are permitted to vary by $\pm 1/2$ in. (13 mm) maximum from level, provided the joint does not slope more than $\pm 1/4$ in. (6.4 mm) in 10 ft (3048 mm). This requirement also applies to the top surface of bearing walls.

28.5.7.2.2 Plumb and Alignment Tolerances

The alignment and out-of-plumb tolerances required by the MSJC Specification are intended to ensure structural performance. In these cases, the intention is to limit the eccentricity of applied loads and thereby not reduce the load-carrying capacity of a given element. These tolerances are shown in Figure 28.10. Walls, columns, and other masonry building elements are required to be constructed to within $-1/4$ in. (6.4 mm) or $+1/2$ in. (13 mm) from the specified dimensions in cross-section and elevation. Masonry walls, columns, and other building elements may not vary from plumb by more than $\pm 1/2$ in. (13 mm) maximum while maintaining a slope of less than $\pm 1/4$ in. (6.4 mm) in 10 ft (3048 mm) and $\pm 3/8$ in. (9.5 mm) in 20 ft (6096 mm). Masonry building elements should also stay true to a line within these same tolerances. Columns and walls continuing from one story to another may vary in alignment by $\pm 3/4$ in. (19 mm) for nonloadbearing walls or columns and by $\pm 1/2$ in. (13 mm) for bearing walls or columns.

28.5.7.2.3 Location of Elements

For continuity of construction and to facilitate the connection of discrete elements, the MSJC Specification requires masonry members to be located within a maximum distance of $\pm 3/4$ in. (19 mm), not exceeding $\pm 1/2$ in. (13 mm) in 20 feet (6096 mm), from their intended location in plan as shown in

FIGURE 28.9 Mortar joint tolerances. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

Figure 28.11. Such tolerances also minimize unanticipated eccentricity of axial loads. Masonry building elements must also be located within $\pm 1/4$ in. (6.4 mm) per story height without exceeding the $\pm 3/4$ -in. (19-mm) maximum. This requirement would apply not only to the top of walls or other vertical assemblies but also to discrete elements within an assembly, such as lintels and bond beams.

28.5.7.2.4 Placement Tolerances for Reinforcement

In accordance with the MSJC Specification, the tolerance for the placement of reinforcement in walls and other flexural elements is $\pm 1/2$ in. (13 mm) when the specified effective depth (d), measured from the centerline of the reinforcement to the opposite compression face of the masonry, is 8 in. (203 mm) or less. The tolerance increases to ± 1 in. (25 mm) for d equal to 24 in. (610 mm) or less but greater than 8 in. (203 mm). For d greater than 24 in. (610 mm), the tolerance for the placement of reinforcement is $\pm 1-1/4$ in. (32 mm), as shown in Figure 28.12. Vertical bars must be placed within 2 in. (51 mm) of their specified location measured parallel to the length of the wall for all applications. The placement tolerances for such reinforcement are larger because slight deviations from specified locations have a negligible impact on the out-of-plane structural performance of an assemblage. Although not required by the MSJC Specification, to facilitate the placement of reinforcement and achieve the required placement tolerances reinforcing bar positioners may be used for both horizontal and vertical reinforcement, although bar positioners may hinder high-lift grouting procedures.

28.6 Testing and Inspection

Design of masonry, as with other construction materials, does not warrant great precision in its analysis and application. A thorough understanding of the materials, their compatibility, and proper detailing is just as important as design precision for the successful performance of the masonry system. The various

FIGURE 28.10 Alignment tolerances. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

combination of units, mortar, grout, and reinforcement, environmental conditions at the project site, and variations in workmanship are factors that will influence the end result in sometimes unpredictable and uncontrollable ways. To account for the multiple combinations of these variables and the effects they can have on the resulting construction, the design factors of safety in the past were more conservative than permitted for other construction materials. More recently, however, quality control and quality assurance programs have been established by codes and standards to provide a minimum level of confidence in the properties of the final construction. Correspondingly, when such testing and inspection programs are put into use the design of masonry structures becomes more economical. The evaluation of masonry materials generally falls into one of two categories:

- In-plant quality control as required by product standards and individual manufacturer's procedures
- Testing and inspection in the field as governed by building codes and standards

The following discussion focuses on the latter of these evaluation programs as related to verifying material properties, inspecting the masonry system, and implementing a construction quality assurance program in the field.

In the past, masonry testing and inspection could be waived at the option of the designer when the allowable design stresses were reduced by a factor of two, commonly referred to as *half-stress design* or

FIGURE 28.11 Tolerances for locating elements. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

un-inspected design. Within contemporary design standards for masonry this option is no longer available. As a minimum, the MSJC Code and MSJC Specification require certificates of compliance for the materials used in construction. Further, for engineered masonry structures, the MSJC requires as a minimum periodic field inspection to verify that the materials and construction are in compliance with the project specifications. Evaluation of individual masonry materials is covered by applicable ASTM standards, while acceptable workmanship and construction tolerances are addressed by the MSJC Specification. The following sections provide a general overview of the procedures used for testing various materials used in masonry construction and the required inspection procedures to verify acceptable workmanship. Further discussion related to the quality assurance and inspection of masonry is offered in *Testing and Inspection of Concrete Masonry Construction* (NCMA, 2006c).

28.6.1 Quality Assurance Levels

The MSJC Specification outlines three levels of quality assurance, each triggered by the design method used and importance of the structure, to ensure a minimum level of quality and safety. These inspection and testing programs are in turn incorporated into the IBC, although they are designated differently. The three levels of quality assurance include:

- *Level A (IBC Basic)*—These requirements are composed of the minimum quality assurance provisions as summarized in Table 28.9 and are only applicable to empirically design masonry, glass unit masonry, and masonry veneer used in the construction of structures designated as nonessential by the building code.

FIGURE 28.12 Placement tolerances for reinforcement. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

- *Level B (IBC Level 1)*—These requirements provide a periodic-type inspection for engineered masonry used in nonessential facilities (as defined in the building code) and for empirically designed masonry, glass unit masonry, and masonry veneer used in essential facilities as summarized in Table 28.10.
- *Level C (IBC Level 2)*—These comprehensive inspection procedures are required for essential facilities (as defined in the building code) that are designed by engineered design methods (allowable stress or strength design) as summarized in Table 28.11. Items inspected under a Level C quality assurance program are similar to those of Level B, with the added requirement that inspection must be continuous during all phases of masonry construction.

These inspection levels are minimum criteria and may be increased when deemed necessary by the owner or designer due to the relative importance or potential hazard of unique structures. In this case, the contract documents must indicate the inspection level and tests that are required to ensure that the masonry work conforms with the project requirements.

In the context of the MSJC requirements, inspection, in combination with material testing, comprises the quality assurance program as established by the administrative and procedural requirements of the contract documents. Current code provisions, however, are vague regarding the minimum qualifications for masonry inspectors conducting routine inspection tasks. Some equate qualification with a nationally recognized certification, while others have allowed a noncertified individual with sufficient experience

Verify compliance with the required inspection provisions of the contract documents and the approved submittals.

to serve as an inspector. As a minimum, however, a masonry inspector must be familiar with masonry materials and construction and be able to read plans and specifications effectively to judge whether or not the construction is in conformance with the contract documents. The following sections provide a brief review of the basic masonry knowledge necessary to effectively implement a testing and inspection program.

28.6.2 Mortar Testing

Reviewed earlier in this chapter were the requirements for mortar materials and their properties, as well as guidelines for selecting mortar types for specific projects. The following discussion addresses the physical testing and assessment of masonry mortars based on standardized tests as outlined in ASTM C 780, *Standard Test Method for Preconstruction and Construction Evaluation of Mortars for Plain and Reinforced Unit Masonry* (ASTM, 2006e). The quality assurance testing of masonry mortars remains one of the most commonly misinterpreted construction procedures. When mortar testing is required for a specific project, it is essential that all parties involved possess a thorough knowledge of the mortar specifications, test methods, and standard practices prior to the start of construction. Misinterpretations of these standards can result in improper testing and confusion regarding compliance with specifications.

The two methods of specifying masonry mortars in accordance with ASTM C 270, *Standard Specification for Mortar for Unit Masonry* (ASTM, 2005d), are the *proportion specification* and the *property specification*. These two compliance options are completely independent and cannot be used in conjunction with one another. Due to its ease of implementation, and because it is the default compliance method in ASTM C 270, the proportion specification is much more commonplace. Although field testing of the mortar is not required to demonstrate compliance with the proportion specification, proportion-batched mortar may be visually documented in the field or sampled and physically evaluated to verify its consistency throughout the job. Although compressive strength testing is the most common physical evaluation technique, several other testing options exist. The most important aspect of mortar quality control, however, is ensuring its consistency throughout the construction project, not the absolute value of a particular property.

The test methods outlined in ASTM C 780 are solely intended to evaluate mortar consistency, which in turn may be compared to baseline preconstruction physical properties of laboratory-prepared mortars but cannot be compared to the values required by the ASTM C 270 property specification. Further, without preconstruction baseline evaluation of mortar properties comparing laboratory-prepared mortar to field-prepared mortar, quantitative acceptance criteria for field mortars cannot be established, as ASTM does not publish minimum physical properties for field-prepared mortar. ASTM C 780 outlines several tests for the field evaluation of masonry mortars, including consistency by cone penetration, consistency retention by cone penetration, consistency by modified concrete penetrometer, aggregate ratio, water content, air content, compressive strength, and splitting tensile strength (see Figure 28.13). Due to its

FIGURE 28.13 Masonry mortar cubes. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

common use, however, the compressive strength evaluation of masonry mortars is reviewed in detail here. Additional guidance on the evaluation of field mortars is provided in ASTM C 1586, *Standard Guide for Quality Assurance of Mortars* (ASTM, 2005a), for those interested in applying alternative quality control techniques.

One of the most universally recognized properties of masonry is compressive strength. Although this property may not be the most important property for masonry mortar, it is often perceived as such in part because compressive strength values are generally understood and are relatively easy to determine. Confusion and misinterpretation sometimes exist, however, when interpreting project specification requirements and field testing results for mortar strength because ASTM standards do not include minimum requirements for field-prepared mortars. One primary reason for the necessary absence of minimum properties of field mortars is that, when fresh mortar is placed on masonry units during construction, its characteristics immediately begin to change due to water absorption by the masonry unit which lowers its water-to-cement ratio and increases its net compressive strength. Because ASTM C 780 tests are performed on mortars that have not been exposed to such absorption conditions, the resulting tested properties are expected to differ significantly from mortar in contact with masonry units. Conversely, ASTM C 270 test methods attempt to simulate this reduced water-to-cement ratio by reducing the amount of water added to the laboratory-prepared mix. The resulting laboratory-prepared mortar would be virtually unusable from a mason's perspective due to its lack of workability.

Because conditions of the units and environment can vary greatly from job to job, the properties of the plastic mortar may have to vary as well to ensure quality construction. It is for this reason that no standardized pass/fail criteria exist for field tests of mortar as well as no standardized correlation between field- and laboratory-prepared mortars. Thus, the mortar compressive strength determined in a laboratory is not directly indicative of the strength of the mortar in the wall, the mortar strength evaluated in accordance with ASTM C 780, or of the masonry assembly strength. Instead, compressive strength sampling of field mortars for quality control is a quantitative measurement of the consistency of the mortar on a project.

Although the physical process of sampling and testing masonry mortar compression specimens is understood well enough, the discussion above highlights some of the common interpretations with their use. As an alternative to mortar compression testing, the mortar aggregate ratio test of ASTM C 780, which determines the approximate relative amounts of cementitious materials to aggregate in the mortar mix, can be a very effective tool for determining the batch-to-batch mortar consistency throughout a project. The added benefit of the aggregate ratio test is that results can be obtained the same day, instead of the days or weeks that may be necessary for compression testing, thus allowing for potential problems to be identified early.

28.6.3 Grout Testing

Quality control of masonry grout typically involves:

- Conducting slump tests on the plastic grout prior to placement to ensure proper consistency and flowability
- Collecting samples to mold specimens for compression testing

The slump test can be used to give an indication of the consistency, water-to-cement ratio, and fluidity of the grout batch. As with concrete, slump testing of masonry grout is conducted in accordance with ASTM C 143, *Standard Test Method for Slump of Hydraulic-Cement Concrete* (ASTM, 2005h). When the grout lift height exceeds 5 ft (1.52 m), but is not greater than 12.67 ft (3.9 m), the grout slump must be maintained between 10 and 11 in. (254 and 279 mm). For grout lift heights of 5 ft (1.52 m) or less, the slump is permitted to vary between 8 and 11 in. (203 and 279 mm). The MSJC recognizes the need to vary grout slump from one project to another based on specific circumstances and as such permits this relatively wide range of grout slumps.

FIGURE 28.14 Molding of grout compression specimen. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

Selecting an appropriate slump for the placement of grout is more art than science. In general, when the rate of water loss from the grout is high, such as when temperatures are elevated or when the masonry units are highly absorptive, slumps in the upper part of the range (i.e., more fluid) may be desirable, although care should be taken that the grout does not segregate because it contains too much water. High-slump grouts are also advantageous when grout spaces are small or highly congested; conversely, when placing grout during relatively cold or wet weather, grouts in the lower slump range are a good choice, as excessive free water is not lost to the masonry units. When grout compressive strength testing is required, the procedures of ASTM C 1019, *Standard Test Method for Sampling and Testing Grout* (ASTM, 2005f), are used. ASTM C 1019 contains procedures for both field and laboratory grout compression testing and can be used either to help select grout proportions during preconstruction or as a quality control test for grout compressive strength during construction.

When used as part of a quality assurance program, the frequency of sampling grout specimens should be specified before the start of construction. Grout specimens are formed in molds made from masonry units with the same absorption and moisture content characteristics as those being used on the job, as shown in Figure 28.14. The purpose of the absorptive mold is to subject the plastic grout to water-loss conditions similar to those in the masonry assembly. Using plastic cylinders or other nonabsorbent means of molding grout compression specimens keeps the water-to-cement ratio in the grout artificially high, resulting in reduced compressive strength measurements. Per ASTM C 476, *Standard Specification for Grout for Masonry* (ASTM, 2002), the minimum compressive strength of masonry grout is 2000 psi (13.79 MPa); however, project requirements may require higher strengths. For example, when the unit strength method is used to determine the specified compressive strength of the masonry (f'_m), the MSJC Specification requires the compressive strength of the grout to equal or exceed f'_m but not be less than 2000 psi (13.79 MPa). As an economic rule of thumb, unless structural criteria dictate otherwise, it is best to balance the specified grout strength with the specified concrete masonry assembly strength so one element of the system is not considerably stronger than the other, resulting in material overstrength and design conservatism. As a final note, when using the strength design provisions of the MSJC Code (not the allowable stress design provisions), a maximum specified grout compressive strength of 5000 psi (34.47 MPa) for concrete masonry construction is applied. This limitation is based solely on the specified compressive strength of grout and does not limit the actual field-tested grout compressive strength. Additional discussion on the sampling and testing of masonry grouts is provided in *Testing and Inspection of Concrete Masonry Construction* (NCMA, 2006c).

28.6.4 Masonry Unit Testing

The physical properties of concrete, clay, and autoclaved aerated concrete masonry units are each evaluated under their own unique standards; ASTM C 140 (ASTM, 2006f), ASTM C 67 (ASTM, 2007b), and ASTM C 1386 (ASTM, 1998), respectively. In addition to these testing standards, some masonry units may require additional evaluation as required by ASTM C 476 (ASTM, 2002) for linear drying shrinkage potential or ASTM C 744 (ASTM, 2005e) for prefaced concrete masonry units. Each standard contains procedures specific to the type of masonry unit being evaluated. Tests addressed by the standards include frequency and methods of sampling, measurement of dimensions, absorption and density calculations, and determination of compressive strength. Each physical property, in turn, must comply with the associated ASTM specification for the unit being evaluated; for example, conventional loadbearing concrete masonry units tested in accordance with ASTM C 140 must meet the minimum specified requirements of ASTM C 90 (ASTM, 2006c). These requirements may be in addition to project-specific requirements. As shown in the three quality assurance programs outlined in Table 28.9, Table 28.10, and Table 28.11, jobsite sampling of masonry units for physical evaluation is not a default requirement unless the unit strength method of verifying the specified compressive strength of masonry as outlined in Section 28.6.5 is used.

28.6.5 Verifying Compliance with f'_m

Structural performance of masonry is largely dependent upon three key criteria:

- The engineering rationale incorporated into the design of the structure
- The physical characteristics of the materials used in the construction of the structure (i.e., the masonry units, grout, mortar, and reinforcement)
- The quality of the construction used in assembling these components

In proportioning, configuring, and reinforcing a masonry element for a prescribed set of loads, a designer bases these parameters on the minimum specified compressive strength of masonry (f'_m). This minimum value is used throughout the design in accordance with the appropriate masonry code to establish allowable stresses and design strengths for masonry elements. It should be stressed that the specified compressive strength of the masonry is related to but *not* equal to the tested compressive strength of the masonry, which conversely must equal or exceed the specified compressive strength of the masonry. Because masonry construction is a composite assemblage of mortar, units, and grout, testing these materials independently does not provide a direct indication of the compressive strength of the final construction. Instead, quality assurance efforts to document the compressive strength of an assembly are based on representative samples combining each individual material either through direct evaluation or through an established correlation. As such, compliance with the specified compressive strength is verified by one of two methods, the *unit strength method* or the *prism test method*, as required by the MSJC Specification.

28.6.5.1 Unit Strength Method

The unit strength method is often considered to be less expensive and more convenient than constructing and testing masonry prisms; however, the unit strength method also yields more conservative results when compared to the prism test method, especially at the higher range of masonry unit strengths. Further, the unit strength method cannot be used for verifying the compressive strength of AAC masonry assemblies, which is based on the strength of the AAC masonry unit alone. Compliance with f'_m by the unit strength method is based on the net area compressive strength of the concrete or clay masonry units and the type of mortar used. The compressive strength of the masonry assemblage is then established in accordance with Table 28.12 and Table 28.13 for concrete and clay masonry, respectively. Each of these tables is based on established correlations from the MSJC Specification. To use the unit strength method, the following conditions must be met:

TABLE 28.12 Compressive Strength of Concrete Masonry Based on the Compressive Strength of Concrete Masonry Units and Type of Mortar Used in Construction

Net Area Compressive Strength of Concrete Masonry Units, psi (MPa)		Net Area Compressive Strength of Masonry, psi (MPa) ^a
Type M or S Mortar	Type N Mortar	
1250 (8.62)	1300 (8.96)	1000 (6.90)
1900 (13.10)	2150 (14.82)	1500 (10.34)
2800 (19.31)	3050 (21.03)	2000 (13.79)
3750 (25.86)	4050 (27.92)	2500 (17.24)
4800 (33.10)	5250 (36.20)	3000 (20.69)

^a For units of less than 4 in. (102 mm) in height, use 85% of the values listed.

TABLE 28.13 Compressive Strength of Clay Masonry Based on the Compressive Strength of Clay Masonry Units and Type of Mortar Used in Construction

Net Area Compressive Strength of Clay Masonry Units, psi (MPa)		Net Area Compressive Strength of Masonry, psi (MPa) ^a
Type M or S Mortar	Type N Mortar	
1700 (11.72)	2100 (14.48)	1000 (6.90)
3350 (23.10)	4150 (28.61)	1500 (10.34)
4950 (34.13)	6200 (42.75)	2000 (13.79)
6600 (45.51)	8250 (56.88)	2500 (17.24)
8250 (56.88)	10,300 (71.02)	3000 (20.69)
9900 (68.26)	NP ^b	3500 (24.13)
13,200 (91.01)	NP ^b	4000 (27.58)

^a For units of less than 4 in. (102 mm) in height, use 85% of the values listed.

^b NP, not permitted.

- Masonry units must comply with ASTM C 55 or ASTM C 90 for concrete masonry or ASTM C 62, ASTM C 216, or ASTM C 652 for clay masonry.
- The thickness of the mortar bed joints cannot exceed 5/8 in. (15.9 mm).
- Mortar must comply with the requirements of ASTM C 270.
- For grouted masonry construction, the grout must meet either the requirements of ASTM C 476 or have a compressive strength equal to or greater than f'_m but not less than 2000 psi (13.79 MPa).

Although the unit strength method offers an easy-to-implement alternative to prism construction, as noted earlier, it can be conservative, particularly for higher material strengths. Table 28.12, for example, would permit an f'_m value of 3000 psi (20.69 MPa) for a 4800-psi (33.10-MPa) concrete masonry unit laid in Type S mortar. If this combination of unit compressive strength and mortar were to be used to construct and test a masonry prism, the actual measured compressive strength would be expected to be in the range of 3800 to 4000 psi (26.20 to 27.58 MPa), considerably higher than the permitted 3000 psi (20.69 MPa).

28.6.5.2 Prism Test Method

The second method for verifying the compressive strength of masonry per the MSJC Specification is the prism test method, which directly measures the compressive strength of a masonry prism constructed using the actual materials used in construction. Masonry prisms are constructed and tested in accordance with ASTM C 1314, *Standard Test Method for Compressive Strength of Masonry Prisms* (ASTM, 2003b), which outlines standardized procedures to construct, cure, transport, and test masonry prisms in compression. At the prescribed frequency as dictated by the MSJC Specification or the project specifications, one set of prisms (each set contains three individual prisms) is constructed for each combination of materials and each testing age for which the compressive strength is to be determined. Units are laid in

FIGURE 28.15 Masonry prism construction. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

stack bond (even if the corresponding construction is in running bond) on a full mortar bed using mortar representative of that used in the corresponding construction. All units used in the prisms must be of the same configuration and oriented in the same manner so webs and face shells are properly aligned. Mortar joints are cut flush regardless of the type of tooling used in construction. These specific construction techniques help to standardize the resulting compressive strength measurements. Once constructed, the prisms are cured in sealed plastic bags to ensure uniform hydration of the mortar and, if used, the grout. Under actual field conditions, longer periods may be required for hydration and the corresponding strengths to be achieved; however, curing prisms in sealed plastic bags results in measured strengths that are representative of those exhibited by the masonry throughout the life of the structure. As with the standardized construction procedures, bag curing also provides uniform and repeatable results. Where the corresponding construction is to be grouted solid, grout solid each prism using grout and consolidation techniques representative of that being used in the corresponding construction. Conversely, if the corresponding construction is to be partially grouted, two sets of prisms are constructed; one set is grouted, and the other is left ungrouted. The average measured compressive strengths of both the ungrouted and grouted prisms are required to meet the specified compressive strength of masonry f'_m per the MSJC Specification.

As an alternative to constructing prisms using full-size units, ASTM C 1314 permits reduced-size units to be used in prism construction, as shown in Figure 28.15. The only criteria for constructing prisms out of reduced-sized units is that hollow units must contain fully closed cells, the cross-section should be as symmetrical as possible, and the final length of the prism should not be less than 4 in. (102 mm). The use of reduced-size prisms, particularly in grouted masonry construction, can significantly reduce the weight of the specimens, which in turn facilitates transporting, handling, and testing the prisms accurately and without damage.

When documenting compliance with f'_m , prisms are typically tested at an age of 28 days, but a different testing age may be designated depending on the requirements of each project. When earlier compressive strength results are desired, a correlation between the 28-day compressive strength and earlier compressive

TABLE 28.14 Masonry Prism Correction Factors

Height/thickness	1.3	1.5	2.0	2.5	3.0	4.0	5.0
Correction factor	0.75	0.86	1.0	1.04	1.07	1.15	1.22

strengths can be established for each project, provided the materials and construction techniques do not change. Because masonry units are available in a wide array of shapes and sizes, the resulting size and configuration of the masonry prism also changes. To provide a standardized means of accounting for the influence that varying prism configurations can have on measured compressive strengths, ASTM C 1314 requires that the measured compressive strength be multiplied by a correction factor as shown in Table 28.14. These correction factors are applied to the measured prism compressive strength prior to reporting.

Unlike clay and concrete masonry, AAC masonry does not employ prism testing. Because the compressive strength of the AAC masonry unit is the lowest compressive strength material in the masonry assemblage, the specified compressive strength of masonry (f'_{AAC}) is simply taken as being equal to or less than the compressive strength of the AAC masonry unit.

28.7 General Detailing

The proper function of a masonry structure resides in the practice and implementation of good detailing and construction. This topic in and of itself can fill volumes; however, a few key detailing considerations are covered here. For a full review of proper detailing of masonry structures, see NCMA (2003a).

28.7.1 Movement Control and Control/Expansion Joints

Cracking in masonry construction can result from many sources. Effective abatement of cracking, from both structural and nonstructural causes, requires a comprehensive understanding of the materials, how they age, and how they respond to movement. The primary sources of cracking in masonry construction include:

- Drying shrinkage of concrete masonry
- Fluctuations in temperature
- Carbonation of cementitious materials
- Differential movement between materials
- Excessive deflection
- Structural overload
- Settlement
- Expansion of clay masonry units

To accommodate small amounts of anticipated movement, control joints or expansion joints are incorporated into masonry construction to relieve built-up stresses (Figure 28.16). For concrete masonry construction, which over an extended period of time will have a net reduction in volume as it shrinks, control joints are placed at regular intervals and at locations of stress concentration to allow the assembly to move without cracking. Clay masonry, conversely, will slowly expand over time as the units absorb water from the environment. As such, clay masonry assemblies incorporate expansion joints to allow the masonry to expand freely without cracking. A comprehensive review of expansion and control joints is provided in BIA (2005) and NCMA (2005a).

28.7.2 Moisture Migration and Detailing

Either as a result of improper detailing or poor construction quality, the water-penetration resistance of masonry structures continues to concern far too many building occupants, despite long-standing recommendations for the proper design, construction, and care of masonry assemblies. Moisture most often

FIGURE 28.16 Concrete masonry control joint. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

enters into a masonry assembly via wind-driven rain or improperly detailed joints and connections, but it can also present itself through capillary suction and water vapor transmission. To ensure proper performance and comfort for the occupants, masonry walls must be detailed to allow water that does enter into the assembly to exit again in a controlled manner. For hollow unit construction and cavity wall construction, this means incorporating flashing at each horizontal discontinuity to collect the water and drain it to the exterior of the wall, as shown in Figure 28.17. In addition to flashing strategies, the use of surface coatings or sealants on the exterior of a masonry assembly offers a second line of defense against water migrating through the surface of the masonry. Sealants, however, do not protect against water entering through improperly designed or built joints or connections and therefore should not be solely relied upon for water penetration resistance. A comprehensive review of effective water mitigation techniques is offered in NCMA (2004a, 2006d) and BIA (2005).

28.8 Project Specifications

Specifications for masonry have the same requirement for clarity and specifics as other construction materials. Standard specifications, such as those published by ASTM, may be used for materials, but the specification for masonry construction must be addressed through project-specific requirements uniquely

FIGURE 28.17 Flashing strategies for masonry. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

adapted to each project. Specifications must be thorough and at a minimum cover the materials, work, testing and inspection, coordination, and methods selected for each project. One of the most comprehensive generic masonry specifications is the *Annotated Guide to Masonry Specification* (TMS, 2000). This document provides a comprehensive, generic specification for masonry construction along with additional discussion and commentary to guide the user in the selection of project-specific requirements.

28.9 Structural Design

28.9.1 Design Methodologies

The structural design of masonry structures in the United States is governed by the provisions of *Building Code Requirements for Masonry Structures* (ACI Committee 530, 2005) in combination with the requirements of the locally adopted building code. The MSJC Code further stipulates that when the locally adopted building code does not contain the appropriate loading criteria for design the provisions of ASCE 7, *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2005), should be used. In the context of today's structural design environment, in which the majority of the United States has adopted and enforced the International Building Code (ICC, 2006a), the structural design of masonry is governed by the MSJC Code as augmented by the IBC and ASCE 7. The following summary focuses on the requirements of the 2005 MSJC Code. The user is cautioned to review the provisions of the locally adopted building code for any applicable modifications to these provisions.

The structural design methods address by the MSJC Code include:

- *Empirical design* is also referred to as *non-engineered design* because it does not explicitly take into account applied design loads on the structure. The roots of empirical design extend back several centuries, when successful forms of construction were used as a model for subsequent projects. The contemporary practice of empirical design limits, design spans, and member sizes is based in large part on the successful use of these rules-of-thumb guidelines developed over several centuries. Because the empirical design method does not explicitly take into consideration modern design loads, its use is not permitted in areas of anticipated high wind or seismic events. Further, because of its historical basis, empirical design is limited to only conventional concrete and clay masonry materials.
- *Allowable stress design* is also referred to as *working stress design* because the stresses in the masonry are limited to the allowable, or working, level of serviceability stresses by code-imposed factors of safety. Allowable stress design is the most commonly used engineered design method for masonry today due in part to its relative ease in application and also because, although the design provisions are under constant maintenance to reflect the latest state-of-the-art design, the basic methodology has remained unchanged for many decades. As of the 2005 edition of the MSJC Code, the allowable stress design provisions applied only to conventional concrete and clay masonry construction.
- *Strength design* is very similar in concept and application to the strength design method used for reinforced concrete. Although various strength design provisions for masonry have been in existence for several decades, it was first introduced into the MSJC Code in 2002. The 2005 MSJC strength design provisions apply to conventional concrete and clay masonry, prestressed masonry, and AAC masonry materials.
- *Prescriptive detailing* (or *deemed-to-comply design*), in addition to the empirical and engineered design methods outlined in the MSJC Code, is addressed in the MSJC. As of the 2005 edition of the MSJC Code, the prescriptive design requirements are predominately limited only to masonry veneers, although several prescriptive good practices are still included in each of the engineered design methods. Several prescriptive design requirements for the structural design of residential masonry construction are contained in the International Residential Code (ICC, 2006b). Where appropriate, the code-required prescriptive design and detailing requirements are reviewed.

Both the allowable stress and strength design provisions address unreinforced and reinforced masonry construction. The distinction between unreinforced and reinforced masonry design is not the presence of reinforcement, as unreinforced masonry may actually have reinforcement present; instead, the design model for unreinforced masonry takes into consideration the flexural resistance of the masonry, neglecting the presence of any reinforcement present. Conversely, reinforced masonry design assumes that the reinforcement carries all tension stresses and assumes that the masonry is cracked. Each of these design methodologies is briefly reviewed in this section. Several comprehensive design guides are available covering the allowable stress and strength design provisions of the MSJC Code, including *Masonry Structures, Behavior and Design* (Drysdale et al., 1999) and the *Masonry Designer's Guide* (TMS, 2007), which reviews each section of the MSJC Code in detail while providing design examples and interpretation guidance. As such, the information presented here only briefly reviews these structural design provisions as they apply to masonry.

28.9.2 Prescriptive Seismic Detailing

Unlike other common design loads, including wind, soil, and live and dead loads, the design of masonry for earthquake loads assumes an inelastic response of the masonry structure during the seismic event. The one exception to this is for unreinforced masonry, which must remain uncracked for all loading conditions. To provide a minimum level of performance during an earthquake, the MSJC Code outlines minimum prescriptive design and detailing requirements for masonry as a function of the assumed seismic risk and expected level of structural ductility assumed during design. The minimum design and

TABLE 28.15 Seismic Detailing Requirements for Masonry Shear Wall Systems

Shear Wall Designation	MSJC Section Reference Design Method	Reinforcement Requirements	Use Permitted in Seismic Design Category
Empirical masonry shear walls	Section 5.3	None	A
Ordinary plain (unreinforced) masonry shear walls	Section 2.2, Section 3.2, or Chapter 4	None	A and B
Detailed plain (unreinforced) masonry shear walls	Section 2.2 or Section 3.2	Section 1.14.2.2.2	A and B
Ordinary reinforced masonry shear walls	Section 2.3 or Section 3.3	Section 1.14.2.2.3	A, B, and C
Intermediate reinforced masonry shear walls	Section 2.3 or Section 3.3	Section 1.14.2.2.4	A, B, and C
Special reinforced masonry shear walls	Section 2.3 or Section 3.3	Section 1.14.2.2.5	A, B, C, D, E, and F
Ordinary plain (unreinforced) AAC masonry shear walls	Section A.2	Section 1.14.2.2.6	A and B
Detailed plain (unreinforced) AAC masonry shear walls	Section A.2	Section 1.14.2.2.7	A and B
Ordinary reinforced AAC masonry shear walls	Section A.3	Section 1.14.2.2.8	A, B, C, D, E, and F

detailing requirements for masonry in low- to high-seismic-risk areas are triggered based on the assigned Seismic Design Category of the project. Likewise, some design methods or systems of limited ductility are restricted to projects of lower seismic risk, as shown in Table 28.15. The use of empirical design for sizing members of the lateral-force-resisting system is limited to Seismic Design Category A because the seismic loads are not directly accounted for in the design. Empirical design, however, can be used for designing nonloadbearing partitions up to and including Seismic Design Category C. Likewise, because of the limited ductility offered by unreinforced masonry members, the MSJC Code limits its use in the design of shear walls to Seismic Design Categories A and B only; hence, for projects of moderate to high seismic hazard, reinforced masonry is required for the design of elements that are part of the lateral-force-resisting system. The follow sections provide a general overview of the prescriptive seismic detailing requirements of the MSJC Code for both loadbearing and nonloadbearing masonry elements. It should be stressed that the prescriptive seismic reinforcement are minimums and may be less than that required to resist earthquake-induced loads.

28.9.2.1 Seismic Detailing Requirements for Nonloadbearing Elements

When incorporated into structures assigned to Seismic Design Category C, D, E, or F, masonry partition walls and other nonloadbearing masonry elements that are not designed to resist loads (other than those induced by their own mass) are required to be isolated from the lateral-force-resisting system. This helps to ensure that forces are not inadvertently transferred between the structural system and the nonstructural system. In addition, the nonstructural elements such as partition walls assigned to Seismic Design Category C and above must be reinforced in *either* the horizontal or vertical direction in accordance with the following and as illustrated in Figure 28.18:

- *Horizontal reinforcement*—Horizontal joint reinforcement is required to consist of at least two longitudinal W1.7 (MW 11) wires for walls having a thickness greater than 4 in. (102 mm). For walls 4 in. (102 mm) thick and less, only one W1.7 (MW 11) wire is required. The spacing of the joint reinforcement is not to exceed 16 in. (406 mm) for either case. Alternatively, bond beams incorporating at least one No. 4 bar (M #13) and spaced no farther apart than 48 in. (1219 mm) may be used instead of bed joint reinforcement. When used, the horizontal reinforcement is to be located within 16 in. (406 mm) of the top and bottom of these masonry walls.
- *Vertical reinforcement*—Vertical reinforcement is required to consist of at least one No. 4 (M #13) bar spaced no more than 48 in. (1219 mm) on-center. Vertical reinforcement must be located within 16 in. (406 mm) of the ends of the masonry wall.

FIGURE 28.18 Minimum prescriptive seismic reinforcement for nonloadbearing masonry elements. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

28.9.2.2 Seismic Detailing Requirements for Detailed Plain (Unreinforced) and Ordinary Reinforced Masonry Shear Walls

Despite their two different names and underlying design methodology, detailed plain (unreinforced) and ordinary reinforced masonry shear walls share the same minimum prescriptive seismic detailing requirements. Detailed plain (unreinforced) masonry shear walls, which are designed as unreinforced elements of a structure, rely entirely upon the masonry to carry and distribute anticipated loads. To ensure a minimum level of performance during a design level earthquake, however, some prescriptive reinforcement is mandated by the MSJC Code for these shear wall types. Similarly, ordinary reinforced masonry shear walls, which are designed in accordance with reinforced masonry procedures, rely upon the reinforcement to carry and distribute anticipated tensile stresses while the masonry carries the compressive stresses. Although ordinary reinforced masonry shear walls contain some reinforcement, to ensure a minimum level of performance during a design-level earthquake, a minimum amount of prescriptive reinforcement is also mandated by the MSJC Code. With very few exceptions, the amount of reinforcement prescriptively required is less than that required by design. Because the reinforcement required by design may also serve as the minimum prescriptive reinforcement, compliance with the minimum prescriptive reinforcement requirements is relatively easy to achieve.

The minimum prescriptive seismic reinforcement for detailed plain (unreinforced) and ordinary reinforced masonry shear walls is summarized in the following and illustrated in Figure 28.19; neither horizontal nor vertical prescriptive reinforcement is required for openings smaller than 16 in. (406

FIGURE 28.19 Minimum prescriptive seismic reinforcement for detailed plain (unreinforced) and ordinary reinforced masonry shear walls. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

mm) in either the horizontal or vertical direction, unless the required prescriptive reinforcement is interrupted by such openings:

- *Vertical reinforcement*—The prescriptive vertical reinforcement is required to consist of at least one No. 4 bar (M #13) at each corner, within 16 in. (406 mm) of each side of openings, within 8 in. (203 mm) of each side of control joints, within 8 in. (203 mm) of the ends of walls, and at a maximum spacing of 120 in. (3048 mm).
- *Horizontal reinforcement*—The minimum prescriptive horizontal reinforcement consists of at least two wires of wire size W1.7 (MW 11), with joint reinforcement spaced not more than 16 in. (406 mm) on-center or bond beams containing no less than one No. 4 (M #13) bar spaced not more than 120 in. (3048 mm) apart. Horizontal reinforcement is also required at the bottom and top of wall openings. Such reinforcement must extend at least 24 in. (610 mm) or 40 bar diameters, whichever is greater, past the opening. Structural reinforcement located at roof and floor levels is required to be continuous. The horizontal reinforcing bar located closest to the top of the wall must be placed within 16 in. (406 mm) of the top of the wall.

28.9.2.3 Seismic Detailing Requirements for Intermediate Reinforced Masonry Shear Walls

Like ordinary reinforced masonry shear walls, intermediate reinforced masonry shear walls are designed in accordance with the reinforced masonry design procedures and contain a minimum amount of reinforcement to ensure a minimum level of performance and ductility during a design-level earthquake. As shown in Figure 28.20, the prescriptive reinforcement for intermediate reinforced masonry shear walls is the same as for ordinary reinforced masonry shear walls, except that the maximum spacing of the vertical reinforcement is reduced to 48 in. (1219 mm).

*In lieu of bond beams with No. 4 bars (M #13) at 120 in. (3048 mm) on-center, provide two wires of wire size W1.7 (MW 11) joint reinforcement at 16 in. (406 mm) on-center.

FIGURE 28.20 Minimum prescriptive seismic reinforcement for intermediate reinforced masonry shear walls. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

28.9.2.4 Seismic Detailing Requirements for Special Reinforced Masonry Shear Walls

Special reinforced masonry shear walls provide the most assumed ductility of all the various shear wall types and concurrently contain the most prescriptive reinforcement of all the various masonry shear-wall types. As such, special reinforced masonry shear walls are permitted in any seismic design category. Due to the large quantities of prescriptive horizontal reinforcement, control joints are typically not necessary for special reinforced masonry shear walls. As shown in Figure 28.21, the prescriptive reinforcement for special reinforced masonry shear walls is required to comply with the requirements for intermediate reinforced masonry shear walls and the following:

- The sum of the cross-sectional area of horizontal and vertical reinforcement shall be at least 0.002 times the gross cross-sectional area of the wall, and the minimum cross-sectional area in each direction shall be not less than 0.0007 times the gross cross-sectional area of the wall. The maximum spacing of vertical and horizontal reinforcement shall be the smallest of one third the length of the shear wall, one third the height of the shear wall, or 48 in. (1219 mm) and shall be uniformly distributed. The minimum cross-sectional area of vertical reinforcement shall be one third of the required horizontal reinforcement. All horizontal reinforcement shall be anchored around the vertical reinforcement with a standard hook.
- Stack bond masonry shear walls assigned to Seismic Design Category D, E, or F are required to be constructed of fully grouted open-end units, fully grouted hollow units laid with full head joints, or solid units. The maximum spacing of reinforcement for stack bond masonry shear walls assigned to Seismic Design Category D is 24 in. (610 mm). Stack bond masonry shear walls assigned to Seismic Design Category E or F are required to have a horizontal cross-sectional area of reinforcement of at least 0.0025 times the gross cross-sectional area of the masonry at a maximum spacing of 16 in. (406 mm).

FIGURE 28.21 Minimum prescriptive seismic reinforcement for special reinforced masonry shear walls. (Courtesy of the National Concrete Masonry Association, Herndon, VA.)

28.9.3 Empirical Design of Masonry

28.9.3.1 Limitations

As previously reviewed, the use of empirical design for sizing and proportioning structural members is limited to regions of relatively low seismic risk and design wind speeds because the procedures do not directly account for design loads. Instead, the provisions are based on successful construction practices developed over a long period of time in various applications. For seismic design, the empirical requirements are not permitted to be used to design any portion of a structure assigned to Seismic Design Category D or higher. The procedure can be used to design nonloadbearing members that are not part of the lateral-force-resisting structure in Seismic Design Categories B and C. Only in Seismic Design Category A can empirical design be used to design members that are part of the lateral-force-resisting structure. The limits on the use of the empirical design procedures for resisting wind loads is slightly more complex, as it is a function of the building height, exposure conditions, type of masonry element, and basic design wind speed, as shown in Table 28.16.

28.9.3.2 Empirically Designed Shear Walls

The minimum nominal thickness of empirically designed masonry shear walls is required to be no less than 8 in. (203 mm). Shear walls must be provided in two separate planes in each principle axis of the building. The minimum cumulative length of the shear walls in each principle direction must be at least 40% of the longest building dimension in plan. Portions of a masonry wall containing openings or members whose length is less than one half its height are not permitted to be included in the cumulative shear-wall length. As an example, a building measuring 80 × 60 ft (24 × 18 m) in plan must provide 32 ft (9.8 m) of cumulative shear-wall length in each principle direction. The maximum spacing between shear walls is determined based on the type of diaphragm system used in the structure. Shear walls

TABLE 28.16 Wind Speed Limits for Empirical Design

Elements	Building Height, ft (m)	Basic Wind Speed, mph (kph)			
		≤90 (145)	90–100 (145–161)	100–110 (161–177)	>110 (177)
All masonry elements that are part of the lateral-force-resisting system and other exterior masonry elements located 35 ft (11 m) or less above ground	≤35 (11)	Permitted	Permitted	Permitted	Not permitted
Interior masonry elements that are not part of the lateral-force-resisting system in buildings other than enclosed as defined by ASCE 7	>180 (55)	Not permitted	Not permitted	Not permitted	Not permitted

Metal deck with concrete fill	3:1
Metal deck with no fill	2:1
Wood	2:1

supporting more rigid diaphragms are permitted to be spaced farther apart than shear walls supporting relatively less rigid diaphragms, as shown in Table 28.17. When the diaphragm is part of a roof supported by empirically designed shear walls, the roof construction is required to be provided with ties or other means so out-of-plane thrust is not imparted to the walls under roof gravity loads.

28.9.3.3 Axial Compression

Contrary to the engineered design procedures for masonry, axial compressive stresses in empirical design are based on the specified gross cross-sectional area of masonry instead of the net cross-sectional area. Further, because of the inherent limits imposed on the use of empirically designed masonry in regions of moderate to high wind and seismic risk, the axial compressive loads are calculated based solely on dead and live loads. The MSJC Code provides allowable compressive stresses for empirically designed masonry based on masonry unit type (concrete, clay, or stone), mortar type, and construction type (single- or multiple-wythe construction). Table 28.18 outlines the allowable gross area compressive stresses for solid and hollow concrete masonry units. For values of masonry strengths between those listed, the MSJC Code does permit linear interpolation of allowable compressive stresses. In addition to the allowable compressive stresses, the empirical design procedures also require that bearing walls of one-story buildings have a minimum nominal thickness of 6 in. (152 mm), whereas bearing walls supporting more than one story have a nominal thickness of not less than 8 in. (203 mm). Because the empirical design provisions for masonry assume that no reinforcement is present, axial tension is not permitted to be carried by empirically

TABLE 28.18 Allowable Compressive Stresses for Empirical Design of Single Wythe Concrete Masonry

Construction and Compressive Strength of Masonry Unit (Gross Area), psi (MPa)	Allowable Compressive Stresses Based on Gross Cross-Sectional Area, psi (MPa)	
	Type M or S Mortar	Type N Mortar
Solid masonry of solid concrete masonry unit:		
3000 (20.69) or greater	225 (1.55)	200 (1.38)
2000 (13.79)	160 (1.10)	140 (0.97)
1200 (8.27)	115 (0.79)	100 (0.69)
Masonry of hollow loadbearing units:		
2000 (13.79) or greater	140 (0.97)	120 (0.83)
1500 (10.34)	115 (0.79)	100 (0.69)
1000 (6.90)	75 (0.52)	70 (0.48)
700 (4.83)	60 (0.41)	55 (0.38)

designed masonry elements. (The MSJC Code does not permit unreinforced masonry elements to carry axial tension but does permit unreinforced masonry elements to carry flexural tension.) When axial tension exists in the masonry, alternative means must be provided to carry these loads.

28.9.3.4 Lateral Support

The lateral support of simply-supported masonry walls in either the horizontal or vertical direction is limited to the ratios summarized in Table 28.19. When the masonry is assumed to be spanning horizontally, the lateral support is required to be provided by cross walls, pilasters, buttresses, or structural framing members. When the masonry is spanning vertically, the lateral support is to be provided by floors, diaphragm roofs, or structural framing members. When computing the ratio for multi-wythe walls, the following thicknesses are used:

- The nominal wall thickness for solid and hollow walls meeting the bonding requirements of the MSJC Code for composite action
- The sum of the nominal thicknesses of each wythe meeting the tie requirements of the MSJC Code for noncomposite action

28.9.3.5 Foundation Walls

The design of foundation walls in accordance with the empirical design procedures are based on the unbalanced backfill height, nominal wall thickness, and construction type as shown in Table 28.20. The use of the empirical design procedures for foundation walls is dependent on the following:

- The wall height does not exceed 8 ft (2.44 m) between lateral supports.
- The terrain around the foundation wall is graded to drain surface water away from the foundation.
- A granular, free-draining backfill is used to prevent hydrostatic pressures.
- The top of the foundation wall is laterally supported prior to backfilling.

TABLE 28.20 Empirically Designed Foundation Walls

Wall Construction	Nominal Wall Thickness, in. (mm)	Maximum Depth of Unbalanced Backfill, ft (m)
Hollow unit masonry	8 (203)	5 (1.52)
	10 (254)	6 (1.83)
	12 (305)	7 (2.13)
Solid unit masonry	8 (203)	5 (1.52)
	10 (254)	7 (2.13)
	12 (305)	7 (2.13)
Fully grouted masonry	8 (203)	7 (2.13)
	10 (254)	8 (2.44)
	12 (305)	8 (2.44)

- The length of the foundation wall between supporting cross walls or pilasters is not greater than 3 times the wall height.
- The masonry is laid in running bond using Type M or S mortar.

28.9.3.6 Miscellaneous Empirical Design Requirements

In addition to the design requirements for shear walls, axial compression, lateral support, and foundation walls, the empirical design requirements address several other topics, including cantilevered and parapet walls, multi-wythe construction, bonding of intersecting walls, anchorage requirements for floors and roofs, and chases and recesses. The reader is referred to the MSJC Code (ACI Committee 530, 2005) for information on these other design topics using the empirical design provisions.

28.9.4 Allowable Stress Design of Masonry

The most widely used structural design method for masonry structures is the allowable stress design procedure, also historically referred to as the *working stress design method*. The following discussion highlights several common aspects of allowable stress design as required by the MSJC Code. The basic premise of the allowable stress design method is that code-prescribed design loads cannot exceed code-prescribed allowable loads. The procedure itself is based on the following assumptions and compliance with standard structural engineering mechanics:

- Within the range of allowable stresses, masonry elements satisfy applicable conditions of equilibrium and compatibility of strains.
- Plane sections before bending remain plane after bending; therefore, masonry strain is directly proportional to the distance from the neutral axis.
- Stress is linearly proportional to strain within the allowable stress range.
- For reinforced masonry design, all tensile stresses are resisted by the steel reinforcement; the contribution of the masonry to the tensile strength of the element is ignored.
- The units, mortar, grout, and reinforcement, if present, act compositely to resist applied loads.

Using allowable stress design, masonry elements are sized and proportioned such that the anticipated service level loads can be safely and economically resisted using the specified material strengths. The specified strength of masonry and reinforcement are in turn reduced by appropriate safety factors to allowable stress levels. For load combinations that include wind or seismic loads, the MSJC Code permits these allowable stresses to be increased by one third.

28.9.4.1 Anchorage

The allowable stress design procedures in the MSJC Code contain design provisions for plate, headed, and bent-bar anchor bolts embedded in masonry. When alternative anchor types are used, or when

higher design values are desired, testing in accordance with ASTM E 488 (ASTM, 1996) is required. The design equations for the allowable stress design of anchor bolts embedded in masonry are based on standard breakout models assuming a 45° failure plane. All masonry materials (units, mortar, and grout) are considered effective in resisting the applied loads. For these design equations to provide a reasonable prediction of anchor performance, the MSJC Code requires that all bolts be embedded at least 4 bolt diameters but not less than 2 in. (51 mm). For headed and plate anchors, the embedment length is measured from the surface of the masonry (which includes the thickness of the masonry unit, if applicable) to the bearing surface of the plate or head of the anchor bolt. Similarly, the effective embedment length of bent-bar anchors is measured from the surface of the masonry to the bearing surface of the bent end minus one anchor bolt diameter.

The allowable tension load on masonry anchors is taken as the lesser of Equation 28.1 (masonry-controlled breakout failure) and Equation 28.2 (anchor-controlled failure).

$$B_a = 0.5A_p\sqrt{f'_m} \quad (28.1)$$

$$B_a = 0.2A_b f_y \quad (28.2)$$

where:

B_a = allowable axial force on a headed, plate, or bent-bar anchor (lb, N).

A_p = projected area of failure surface (in.², mm²).

f'_m = specified compressive strength of masonry (psi, MPa).

A_b = cross-sectional area of the anchor bolt (in.², mm²).

f_y = specified yield strength of the anchor bolt (psi, MPa).

For use in Equation 28.1, the projected area on the masonry surface (A_p) is calculated by the lesser of Equation 28.3 or Equation 28.4. In cases when the projected surfaces of adjacent anchor bolts overlap, the MSJC Code requires that the projected area of each bolt be reduced by one half of the overlapping area. This requirement, however, assumes that the projected area of no more than two anchor bolts would intersect. Although rare in masonry construction, where the projected areas of more than two anchor bolts overlap the overlapping areas should be reduced in linear proportion to the number of anchors overlapping a common surface. In all cases, the portion of the projected area falling within an open cell, hollow cavity, or outside of the masonry element should be deducted from A_p :

$$A_p = \pi l_b^2 \quad (28.3)$$

$$A_p = \pi l_{be}^2 \quad (28.4)$$

where:

l_b = effective embedment length of the anchor bolt (in., mm).

l_{be} = anchor bolt edge distance, measured in the direction of load, from the edge of the masonry to the center of the cross-section of the anchor bolt (in., mm).

For headed, plate, or bent-bar anchors having an edge distance greater than or equal to 12 bolt diameters, the allowable shear strength (B_v) is governed by the lesser of Equation 24.5 (masonry-controlled failure) or Equation 24.6 (anchor-controlled failure). Where the anchor bolt edge distance is less than 12 bolt diameters, the allowable shear load is required to be reduced by linear interpolation to a value of zero at an edge distance of 1 in. (25 mm):

$$B_v = 350\sqrt{f'_m A_b} \quad (28.5)$$

$$B_v = 0.12A_b f_y \quad (28.6)$$

Where anchor bolts are subjected to combined tension and shear, the MSJC Code requires the such anchors also be designed to satisfy Equation 28.7. This linear interaction model is recognized as being relatively conservative for anchor bolt design:

$$\frac{b_a}{B_a} + \frac{b_v}{B_v} \leq 1 \quad (28.7)$$

where:

b_a/B_a = ratio of applied to allowable axial force on the anchor bolt.

b_v/B_v = ratio of applied to allowable shear force on the anchor bolt.

28.9.4.2 Development and Splicing

The minimum development lengths for wires and reinforcing bars embedded in masonry are calculated by Equation 28.8 and Equation 28.9, respectively. Equation 28.8 applies to wires in tension only, whereas Equation 28.9 applies to reinforcing bars in tension or compression. In no case is the minimum development length to be less than 6 in. (152 mm) for wires and 12 in. (305 mm) for reinforcing bars:

$$l_d = 0.0015d_b F_s \quad (28.8)$$

$$l_d = \frac{0.13d_b^2 f_y \gamma}{K \sqrt{f'_m}} \quad (28.9)$$

where:

l_d = development length or lap length of reinforcing bar or wire (in., mm).

d_b = diameter of reinforcing bar or wire (in., mm).

F_s = allowable tensile or compressive stress in reinforcement (psi, MPa).

f_y = specified yield strength of reinforcing bar or wire (psi, MPa).

K = lesser of the masonry clear cover to the reinforcement, the clear spacing between adjacent reinforcement (not spliced reinforcing bars), or $5d_b$.

γ = 1.0 for No. 3 (M #10) through No. 5 (M #16) reinforcing bars; 1.3 for No. 6 (M #19) and No. 7 (M #22) reinforcing bars; and 1.5 for No. 8 (M #25) through No. 11 (M #36) reinforcing bars.

Where epoxy-coated wire or reinforcing bars are used, the development length calculated by Equation 28.8 or Equation 28.9 is increased by 50%.

Splicing of reinforcing bars is accomplished by lapping, welding, or mechanically connecting reinforcement. The minimum length for lap-spliced reinforcement is calculated in accordance with Equation 28.9. When welding or providing mechanical couplers, the splice is required to develop no less than 125% of the nominal yield strength of the spliced reinforcement. Although not overtly apparent upon initial inspection, lap splice lengths detailed to comply with Equation 28.9 also meet this minimum yield strength requirement.

28.9.4.3 Unreinforced Masonry Design

For unreinforced masonry, the masonry assembly (units, mortar, and grout if used) is designed to carry all applied stresses. The additional capacity from the inclusion of reinforcing steel, such as reinforcement added for the control of shrinkage cracking or prescriptively required by the code, is neglected. Because the masonry is intended to resist both tension and compression stresses resulting from applied loads, the masonry must be designed to remain uncracked.

28.9.4.3.1 Axial Compression and Flexure

Although unreinforced masonry can be designed to resist flexural tension stresses due to applied loads, unreinforced masonry may not be subjected to net axial tension, such as that due to wind uplift on a roof connected to a masonry wall or due to the overturning effects of lateral loads. Compressive stresses

from dead loads can be used to offset tensile stresses, but where the wall is subject to a net axial tension reinforcement must be incorporated to resist the resulting tensile forces. When masonry walls are subjected to compressive axial loads only, the calculated compressive stress due to the applied load (f_a) must not exceed the allowable compressive stress (F_a) as given by Equation 28.10 or Equation 28.11, as appropriate. For masonry elements with h/r not greater than 99:

$$f_a \leq F_a = \frac{1}{4} f'_m \left[1 - \left(\frac{h}{140r} \right)^2 \right] \quad (28.10)$$

For masonry elements with h/r greater than 99:

$$f_a \leq F_a = \frac{1}{4} f'_m \left(\frac{70r}{h} \right)^2 \quad (28.11)$$

where:

f_a = applied compressive stress in masonry due to axial load only (psi, MPa).

F_a = allowable compressive stress in masonry due to axial load only (psi, MPa).

f'_m = specified compressive strength of masonry (psi, MPa).

h = effective height of masonry element (in., mm).

r = radius of gyration of masonry element (in., mm).

Average and net cross-sectional properties such as radius of gyration, moment of inertia, section modulus, and area are available through various industry publications, including *Section Properties of Concrete Masonry Walls* (NCMA, 2003b).

A further check for stability is also required per Equation 28.12, whereby the axial compressive load (P) is limited to one fourth the buckling load (P_e). The eccentricity of the applied load (e) used to determine P_e in Equation 28.12 is the actual eccentricity of the applied axial load, not an equivalent eccentricity due to an applied bending moment:

$$P \leq \frac{1}{4} P_e = \frac{1}{4} \left[\frac{\pi^2 E_m I_n}{h^2} \left(1 - 0.577 \frac{e}{r} \right)^3 \right] \quad (28.12)$$

where:

P = applied axial load (lb, N).

P_e = Euler buckling load (lb, N).

E_m = modulus of elasticity of masonry (psi, MPa).

I_n = moment of inertia of net cross-sectional area of masonry (in.⁴, mm⁴).

h = effective height of masonry element (in., mm).

e = eccentricity of applied axial load (in., mm).

r = radius of gyration of masonry element (in., mm).

For unreinforced masonry elements subjected to flexural tension, the allowable flexural tension values are prescribed by the MSJC Code, and vary with the direction of span, mortar type, bond pattern, and percentage of grouting, as shown in Table 28.21. For walls spanning horizontally between supports, the code conservatively assumes that masonry constructed in stack bond cannot reliably transfer flexural tension stresses across the head joints. As such, the allowable flexural tension values parallel to the bed joints (perpendicular to the head joints) for stack bond construction are assumed to be zero for design purposes.

TABLE 28.21 Allowable Flexure Tension Stresses, psi (kPa)

Direction of Flexural Tensile Stress and Masonry Type	Mortar Types			
	Portland Cement–Lime or Mortar Cement		Masonry Cement or Air-Entrained Portland Cement–Lime	
	M or S	N	M or S	N
<i>Normal to bed joints</i>				
Solid units	40 (276)	30 (207)	24 (166)	15 (103)
Hollow units: ^a				
UngROUTED	25 (172)	19 (131)	15 (103)	9 (62)
Fully grouted	65 (448)	63 (434)	61 (420)	58 (400)
<i>Parallel to bed joints in running bond</i>				
Solid units	80 (552)	60 (414)	48 (331)	30 (207)
Hollow units:				
UngROUTED and partially grouted	50 (345)	38 (262)	30 (207)	19 (131)
Fully grouted	80 (552)	60 (414)	48 (331)	30 (207)
<i>Parallel to bed joints in stack bond</i>	0 (0)	0 (0)	0 (0)	0 (0)

^a For partially grouted masonry, allowable stresses shall be determined on the basis of linear interpolation between fully grouted hollow units and ungrouted hollow units based on amount (percentage) of grouting.

Because the compressive strength of masonry is much larger than its tensile strength (or mortar–unit bond strength), the strength of unreinforced masonry subjected to net flexural stresses is almost always controlled by the flexural tension values of Table 28.21. For masonry elements subjected to a bending moment (M) and a compressive axial force (P), the resulting flexural bending stress is determined using Equation 28.13:

$$f_b = \frac{Mt}{2I_n} - \frac{P}{A_n} \quad (28.13)$$

where:

f_b = applied stresses due to bending (psi, MPa).

M = applied bending moment (in.-lb, N-mm).

t = specified thickness of masonry element (in., mm).

I_n = moment of inertia of net cross-sectional area of masonry (in.⁴, mm⁴).

P = applied compressive axial load (lb, N).

A_n = net cross-sectional area of masonry element (in.², mm²).

If the value of the bending stress (f_b) given by Equation 28.13 is positive, then the masonry section is controlled by tension and the limiting values of Table 28.21 must be satisfied. Conversely, if f_b as given by Equation 28.13 is negative, the masonry section is in compression and the compressive stress limitation of Equation 28.14 must be met:

$$f_b \leq F_b = \frac{1}{3}f'_m \quad (28.14)$$

When unreinforced masonry elements are subjected to a combination of axial load and flexural bending, a unity equation is used to proportion the available allowable stresses to the applied loads per Equation 28.15:

$$\frac{f_a}{F_a} + \frac{f_b}{F_b} \leq 1 \quad (28.15)$$

28.9.4.3.2 Shear

Shear stresses on unreinforced masonry elements are calculated based on the net cross-sectional properties of the masonry in the direction of the applied shear force using Equation 28.16:

$$f_v = \frac{VQ}{I_n b} \quad (28.16)$$

where:

- f_v = applied shear stress in masonry element (psi, MPa).
- V = applied shear force (lb, N).
- Q = first moment of inertia (in.³, mm³).
- I_n = moment of inertia of net cross-sectional area of masonry (in.⁴, mm⁴).
- b = width of masonry section (in., mm).

Equation 28.16 is applicable to the determination of both in-plane and out-of-plane shear stresses. Because unreinforced masonry is designed to remain uncracked, it is not necessary to perform a cracked section analysis to determine the net cross-sectional area of the masonry.

The calculated shear stress due to applied loads (f_v) as given by Equation 28.16 is taken as the smaller of the following code-prescribed allowable shear stress values (F_v), as applicable:

$$1.5(f'_m)^{0.5}$$

120 psi (827 kPa)

For running bond masonry not grouted solid, $37 + 0.45N_v/A_n$

For stack bond masonry with open end units and grouted solid, $37 + 0.45N_v/A_n$

For running bond masonry grouted solid, $60 + 0.45N_v/A_n$

For stack bond masonry other than open end units grouted solid, 15 psi (103 kPa)

where:

- N_v = compressive force acting normal to the shear plane (lb, N).
- A_n = net cross-sectional area of masonry element (in.², mm²).

Although the MSJC Code designates these allowable shear stress values as being applicable to in-plane shear stresses only, no allowable shear stresses are provided for out-of-plane loads. In light of the absence of out-of-plane allowable shear stress values, the MSJC Code Commentary recommends using the in-plane allowable shear stress values for out-of-plane shear design.

28.9.4.4 Reinforced Masonry Design

The design of reinforced masonry in accordance with the MSJC Code neglects the tensile resistance provided by the masonry units, mortar, and grout in determining the strength of the masonry assemblage and assumes that all tension stresses are resisted by the reinforcement. Thus, for design purposes, the portion of masonry subjected to net tensile stresses is assumed to have cracked. Although the determination of the strength of a reinforced masonry element conservatively assumes the portion of the masonry subjected to net tensile stresses has cracked, this should be verified when establishing the stiffness and deflection of a reinforced masonry element.

28.9.4.4.1 Reinforcement

The tensile stress in the reinforcement due to the applied load (f_s) is calculated as the product of the strain in the steel (which increases linearly in proportion to the distance from the neutral axis) multiplied by its modulus of elasticity (E_s). The modulus of elasticity of mild steel reinforcement (E_s) is assumed to be 29,000,000 psi (200 GPa). The code-prescribed allowable steel stresses are as follows:

- For Grade 60 reinforcement in tension, $F_s = 24,000$ psi (165.5 MPa).
- For Grade 40 and 50 reinforcement in tension, $F_s = 20,000$ psi (137.9 MPa).

FIGURE 28.22 Allowable stress design model for reinforced masonry.

- For wire reinforcement in tension, $F_s = 30,000$ psi (206.9 MPa).
- For all reinforcement in compression, $F_s = 24,000$ psi (165.5 MPa) or $0.4f_y$, whichever is less.

Unless ties or stirrups laterally confine the reinforcement as prescribed by the MSJC Code, the reinforcement is assumed to contribute no compressive resistance to axially loaded elements. For design purposes, the effective width of the compression zone per bar is limited to the smallest of:

- Six times the wall thickness
- The center-to-center spacing of the reinforcement
- 72 in. (1829 mm)

This requirement applies to masonry constructed in running bond and to masonry constructed in stack bond containing bond beams spaced no farther than 48 in. (1219 mm) on-center. Where the center-to-center spacing of the reinforcement does not control the effective width of the compression zone, the resulting resisting moment or resisting shear is proportioned over the width corresponding to the actual reinforcement spacing.

28.9.4.4.2 Axial Compression and Flexure

As with unreinforced masonry, the allowable compressive stress in masonry (F_b) due to flexure or due to a combination of flexure and axial load is limited by Equation 28.14. When axial loads are not present or are conservatively neglected, as may be appropriate in some cases, several circumstances must be considered when determining the flexural capacity of reinforced masonry walls. For a fully grouted element, a cracked transformed section approach is used wherein the reinforcement area is transformed to an equivalent area of masonry using the modular ratio. Partially grouted walls are analyzed in the same way but with the additional consideration of the ungrouted cores. For partially grouted masonry, two types of behavior to consider are:

- When the neutral axis (the location of zero stress) lies within the compression face shell, as shown in Figure 28.22a, the wall is analyzed and designed as if the element were fully grouted.
- When the neutral axis lies within the core area, rather than the compression face shell, as shown in Figure 28.22b, the portion of the ungrouted cells (in partially grouted masonry) must be deducted from the area of masonry capable of carrying compression stresses.

The location of the neutral axis depends on the relative moduli of elasticity of the masonry and steel (n), as well as the reinforcement ratio (ρ) and the distance between the reinforcement and the extreme compression fiber (d). When analyzing partially grouted walls, it is typically assumed that the neutral axis lies within the compression face shell, as the analysis is more straightforward. Based on this assumption, the resulting value of k and the location of the neutral axis (kd) is calculated. If it is determined that the neutral axis lies outside the compression face shell, the more rigorous tee beam analysis is performed; otherwise, the rectangular beam analysis is carried out.

For fully grouted masonry elements and for partially grouted masonry elements with the neutral axis in the compression face shell, the resisting flexural capacity (M_r) is taken as the lesser of M_m (masonry controlled flexural strength) and M_s (reinforcing-steel-controlled flexural strength) calculated as follows:

$$n = \frac{E_s}{E_m} \quad (28.17)$$

$$\rho = \frac{A_s}{bd} \quad (28.18)$$

$$k = \sqrt{2\rho n + (\rho n)^2} - \rho n \quad (28.19)$$

$$j = 1 - \frac{k}{3} \quad (28.20)$$

$$M_m = \frac{1}{2} F_b k j b d^2 \quad (28.21)$$

$$M_s = A_s F_s j d \quad (28.22)$$

where:

n = modular ratio.

E_s = modulus of elasticity of reinforcing steel (psi, MPa).

E_m = modulus of elasticity of masonry (psi, MPa).

ρ = reinforcement ratio.

A_s = cross-sectional area of reinforcement (in.², mm²).

b = width of masonry element (in., mm).

d = effective depth to center of reinforcement (in., mm).

k = ratio of distance between compression face of masonry element and neutral axis to the effective depth (d).

j = ratio of distance between centroid of flexural compressive forces and centroid of tensile forces to depth (d).

M_m = flexural strength (resisting moment) when masonry controls (in.-lb, N-m).

M_s = flexural strength (resisting moment) when reinforcement controls (in.-lb, N-m).

For partially grouted masonry walls where the neutral axis is located within the cores, the resisting flexural capacity (M_r) is calculated using the neutral axis coefficient (k) given by Equation 28.23 and either Case A or Case B as follows:

$$k = \frac{-A_s n - t_{fs}(b - b_w)}{db_w} \quad (28.23)$$

where:

t_{fs} = thickness of face shell of masonry unit (in., mm).

b_w = for partially grouted walls, width of grouted cell plus each web thickness within the compression zone (in., mm).

Case A. For cases where the masonry strength controls the design:

$$f_s = nF_b \left(\frac{1-k}{k} \right) \quad (28.24)$$

where f_s is the calculated stress in reinforcement (psi, MPa). If f_s as determined using Equation 28.24 is greater than the allowable steel stress (F_s), then the strength of the section is controlled by the reinforcement and the masonry element is designed using the procedures outlined for Case B, below. Otherwise, the internal compression force (C) and tension force (T) are computed as follows:

$$C = \frac{1}{2} F_b b k d \quad (28.25)$$

$$T = A_s f_s = A_s n F_b \left(\frac{1-k}{k} \right) \quad (28.26)$$

Case B. For cases where the reinforcement strength controls the design:

$$f_b = \frac{F_s}{n} \left(\frac{k}{1-k} \right) \quad (28.27)$$

$$C = \frac{1}{2} f_b b k d = \frac{1}{2} b k d \left(\frac{F_s}{n} \left(\frac{k}{1-k} \right) \right) \quad (28.28)$$

$$T = A_s F_s \quad (28.29)$$

The resisting bending moment is then calculated by Equation 28.30 as follows:

$$M_r = C \left(\frac{2t_{f_s}}{3} \right) - T \left(d - \frac{k d}{3} - \frac{2t_{f_s}}{3} \right) \quad (28.30)$$

Axial compressive loads acting through the axis of a member are distributed over the net cross-sectional area of masonry supporting the load. The allowable axial compressive force is based on the compressive strength of masonry and the slenderness ratio of the element in accordance with Equation 28.31 or Equation 28.32, as appropriate. Axial tensile loads, conversely, are carried entirely by the reinforcement. For elements with h/r not greater than 99, the allowable compressive force (P_a) is:

$$P_a = \left(0.25 f'_m A_n + 0.65 A_{st} F_s \right) \left[1 - \left(\frac{h}{140r} \right)^2 \right] \quad (28.31)$$

For elements with h/r greater than 99, the allowable compressive force (P_a) is:

$$P_a = \left(0.25 f'_m A_n + 0.65 A_{st} F_s \right) \left(\frac{70r}{h} \right)^2 \quad (28.32)$$

where:

P_a = allowable axial compressive force (lb, N).

A_{st} = total area of laterally tied reinforcement (in.², mm²).

Often, loading conditions result in both axial load and flexure on a wall. Superimposing the stresses resulting from axial compression and flexural compression produces the combined stress. Members are proportioned so this maximum combined stress does not exceed the allowable stress limitations outlined above.

28.9.4.4.3 Shear

Shear acting on masonry flexural members and shear walls is resisted entirely either by the masonry (units, mortar and grout) or by shear reinforcement. This design approach is contrasted by that used for the strength design of reinforcement masonry, which allows the masonry and shear reinforcement to act together in resisting applied shear forces. For masonry members that are not subjected to flexural tension, the allowable shear stresses for unreinforced masonry apply. For masonry elements that are subjected to flexural tension, the applied shear stress is calculated as follows:

$$f_v = \frac{V}{bd} \quad (28.33)$$

Where reinforcement is not provided to resist the entire calculated shear stress, f_v , the allowable shear stress, F_v , is determined in accordance with the following:

For flexural members, $F_v = \sqrt{f'_m} \leq 50$ psi (345 kPa)

For shear walls where $M/Vd < 1$, $F_v = \frac{1}{3} [4 - (M/Vd)] \sqrt{f'_m} \leq 80 - 45(M/Vd)$

For shear walls where $M/Vd \geq 1$, $F_v = \sqrt{f'_m} \leq 35$ psi (241 kPa)

When shear reinforcement is provided to resist the entire shear force, the minimum amount of shear reinforcement is determined by Equation 28.34. Shear reinforcement provided in accordance with Equation 28.34 must also comply with the following:

- Shear reinforcement is oriented parallel to the direction of the shear force.
- Shear reinforcement spacing must not exceed the lesser of $d/2$ or 48 in. (1219 mm).

Reinforcement must also be provided perpendicular to the shear reinforcement. This prescriptive reinforcement must have an area of at least one third A_v as given by Equation 28.34 and may not be spaced farther apart than 8 ft (2438 mm):

$$A_v = \frac{Vs}{F_s d} \quad (28.34)$$

where:

A_v = cross-sectional area of shear reinforcement (in.², mm²).

s = spacing of shear reinforcement (in., mm).

Where reinforcement is provided to resist the entire calculated shear stress, f_v , the allowable shear stress, F_v , is determined in accordance with the following:

For flexural members, $F_v = 3.0 \sqrt{f'_m} \leq 150$ psi (1034 kPa)

For shear walls where $M/Vd < 1$, $F_v = \frac{1}{2} [4 - (M/Vd)] \sqrt{f'_m} \leq 120 - 45(M/Vd)$

For shear walls where $M/Vd \geq 1$, $F_v = 1.5 \sqrt{f'_m} \leq 75$ psi (517 kPa)

In each of the above equations, the ratio of M/Vd must be taken as a positive value.

FIGURE 28.23 Strength design model for reinforced masonry.

28.9.5 Strength Design of Masonry

The following discussion provides a basic overview of design criteria and requirements for masonry structures designed using the strength design provisions contained in Chapter 3 of the MSJC Code. Strength design is based on the following design assumptions in conjunction with basic principles of engineering mechanics:

- Plane sections before bending remain plane after bending; therefore, strain in the masonry and in reinforcement, if present, is directly proportional to the distance from the neutral axis.
- For unreinforced masonry, the flexural stresses in the masonry are assumed to be directly proportional to strain. For reinforced masonry, the tensile strength of the masonry is neglected when calculating flexural strength but considered when calculating deflection.
- The units, mortar, grout, and reinforcement for reinforced masonry act compositely to resist applied loads.
- The nominal strength of masonry cross-sections for combined flexure and axial load is based on applicable conditions of equilibrium.
- The maximum masonry compressive stress is $0.8f'_m$ for both reinforced and unreinforced masonry.
- The maximum usable strain (ϵ_{mu}) at the extreme compression fiber is 0.002 for concrete masonry and 0.0035 for clay masonry.
- For reinforced masonry, reinforcement stresses below the specified yield strength (f_y) are taken equal to the modulus of elasticity of the reinforcement (E_s) times the steel strain (ϵ_s). For strains greater than that corresponding to f_y , stress in the reinforcement is taken equal to f_y .
- For reinforced masonry, the compressive stress is rectangular and uniformly distributed over an equivalent compression zone, bounded by the compression face of the masonry with a depth of $a = 0.80c$.

Based on the assumed design model outlined above, the internal distribution of stresses and strains is illustrated in Figure 28.23 for a reinforced masonry element. Using strength design, the design strength of an element is compared to the factored strength, which includes code-prescribed load factors. The design strength of masonry is the nominal strength multiplied by an appropriate strength reduction factor (ϕ). The design is acceptable when the design strength equals or exceeds the factored strength (i.e., when $\phi M_n \geq M_u$).

28.9.5.1 Strength Reduction Factors

To account for uncertainties in construction, material properties, calculated vs. actual strength and anticipated failure modes, the nominal strength of a masonry element is multiplied by an appropriate strength reduction factor (ϕ). The strength reduction factors are used in conjunction with the load factors applied to the design loads. The values of the strength reduction factors for various types of loading conditions are as follows:

- For reinforced masonry elements subjected to flexure or axial loads, $\phi = 0.90$.
- For unreinforced masonry elements subjected to flexure or axial compressive loads, $\phi = 0.60$.
- For masonry elements subjected to shear loads, $\phi = 0.80$.
- For bearing on masonry elements, $\phi = 0.60$.
- For anchor bolts:
 - Where the nominal strength of the anchor bolt is governed by masonry breakout, $\phi = 0.50$.
 - Where the nominal strength of the anchor bolt is governed by the anchor steel, $\phi = 0.90$.
 - Where the nominal strength of the anchor bolt is governed by anchor pullout, $\phi = 0.65$.

28.9.5.2 Anchorage

The strength design of anchors embedded in masonry is similar in concept to that for allowable stress design, with several key differences in the prescriptive detailing and nominal strengths. Unlike allowable stress design, the MSJC strength design provisions require embedded anchor bolts to have at least 1/2 in. (13 mm) of grout between the bolt and the masonry, except that 1/4-in. (6.4-mm)-diameter anchor bolts are permitted to be placed in mortared bed joints at least 1/2 in. (13 mm) thick. Nominal strengths of headed and bent-bar anchor bolts are determined using the equations outlined in this section. The strength design provisions do not explicitly address plate anchors embedded in masonry construction. Further, when anchor bolts penetrate the face shell of a masonry unit and are designed by the strength design method, the opening in the face shell is required to provide at least 1/2 in. (13 mm) of grout cover around the perimeter of the bolt. This prescriptive detailing requirement is intended to provide a means of inspection to ensure the adequate placement of grout around the anchor bolt and does not influence the design strength of the connection.

The nominal axial tensile strength of headed anchor bolts embedded in masonry (B_{an}) is taken as the smaller of Equation 28.35 (masonry-controlled breakout failure) and Equation 28.36 (anchor-controlled failure). The nominal axial tensile strength of bent-bar anchor bolts embedded in masonry, (B_{an}) is taken as the smallest value of Equation 28.35, Equation 28.36, and Equation 28.37 (anchor pullout failure). The second term in Equation 28.37, which accounts for frictional resistance along the shank of the anchor, is only included in the nominal axial strength calculation if jobsite inspection verifies that the shanks of the bent-bar anchors are free of oil, grease, or other debris that would decrease the bond between the anchor bolt and grout.

$$B_{an} = 4A_{pt}\sqrt{f'_m} \quad (28.35)$$

$$B_{an} = A_b f_y \quad (28.36)$$

$$B_{an} 1.5f'_m e_b d_b + \left[300\pi(l_b + e_b + d_b)d_b \right] \quad (28.37)$$

where:

B_{an} = nominal axial strength of anchor bolt (lb, N).

A_{pt} = projected area of failure surface (in.², mm²).

f'_m = specified compressive strength of masonry (psi, MPa).

A_b = cross-sectional area of the anchor bolt (in.², mm²).

f_y = specified yield strength of the anchor bolt (psi, MPa).

e_b = projected leg extension of the bent-bar anchor, measured from the inside edge of the anchor at bend to farthest point of anchor in the plane of the hook (in., mm).

d_b = diameter of the anchor bolt (in., mm).

l_b = effective embedment length of the anchor bolt, not to be less than 4 bolt diameters or 2 in. (51 mm), whichever is less (in., mm).

For use in Equation 28.35, the projected area on the masonry surface of a right circular breakout cone (A_{pt}) is calculated using Equation 28.38. In cases when the projected surfaces of adjacent anchor bolts overlap, the MSJC Code requires that the projected area of each bolt be reduced by one half of the overlapping area. This requirement, however, assumes that the projected areas of no more than two anchor bolts would intersect. Although rare in masonry construction, where the projected areas of more than two anchor bolts overlap, the overlapping areas should be reduced in linear proportion to the number of anchors overlapping a common surface. In all cases, the portion of the projected area falling within an open cell, hollow cavity, or outside of the masonry element should be deducted from A_{pt} :

$$A_{pt} = \pi l_b^2 \quad (28.38)$$

The nominal shear strength of headed and bent-bar anchor bolts (B_{vn}) is governed by the smaller of Equation 28.39 (masonry-controlled breakout failure) or Equation 28.40 (anchor-controlled failure):

$$B_{vn} = 4A_{pv}\sqrt{f'_m} \quad (28.39)$$

$$B_{vn} \leq 0.6A_b f_y \quad (28.40)$$

Where the projected area on a masonry surface of one half of a right circular cone, A_{pv} is calculated in accordance with Equation 28.41 as follows:

$$A_{pv} = \frac{\pi l_{be}^2}{2} \quad (28.41)$$

Where anchor bolts are subjected to combined tension and shear, the MSJC Code requires that such anchors also be designed to satisfy Equation 28.42; this linear interaction model is recognized as being relatively conservative for anchor bolt design:

$$\frac{b_{af}}{\phi B_{an}} + \frac{b_{vf}}{\phi B_{vn}} \leq 1 \quad (28.42)$$

where:

b_{af} = factored axial force in anchor bolt (lb, N).

b_{vf} = factored shear force in anchor bolt (lb, N).

ϕB_{an} = governing design axial strength of anchor bolt (lb, N).

ϕB_{av} = governing design shear strength of anchor bolt (lb, N).

28.9.5.3 Development and Splicing

Minimum development and lap splice lengths for strength design are nearly identical to those outlined in Section 28.9.4.2 for allowable stress design, with a couple of notable exceptions. The strength design provisions do not explicitly address requirements for the development or splicing of wire reinforcement. Further, the strength design provisions limits the maximum size of reinforcement to No. 9 (M #29) reinforcing bars. With these exceptions, minimum lap splice and development length are calculated in accordance with Equation 28.9.

28.9.5.4 Unreinforced Masonry Design

For unreinforced masonry, the masonry assembly (units, mortar, and grout, if used) is designed to carry all applied stresses. The additional capacity from the inclusion of reinforcing steel, such as reinforcement

added for the control of shrinkage cracking or prescriptively required by the code, is neglected. Because the masonry is intended to resist both tension and compression stresses resulting from applied loads, the masonry must be designed to remain uncracked.

28.9.5.4.1 Axial Compression and Flexure

As with the allowable stress design of masonry, unreinforced masonry designed by the strength design procedures can be used to resist flexural tension stresses due to applied loads; however, unreinforced masonry may not be subjected to net axial tension, such as that due to wind uplift on a roof connected to a masonry wall or due to the overturning effects of lateral loads. Although compressive stresses from dead loads can be used to offset tensile stresses, where the wall is subject to a net axial tension reinforcement must be incorporated to resist the resulting tensile forces. When masonry walls are subjected to compressive axial loads only, the nominal axial strength (P_a) is calculated in accordance with Equation 28.43 or Equation 28.44, as appropriate. For masonry elements with h/r not greater than 99:

$$P_a = 0.8 \left\{ 0.8 A_n f'_m \left[1 - \left(\frac{h}{140r} \right)^2 \right] \right\} \quad (28.43)$$

For masonry elements with h/r greater than 99:

$$P_a = 0.8 \left\{ 0.84 A_n f'_m \left(\frac{70r}{h} \right)^2 \right\} \quad (28.44)$$

where:

- P_a = nominal axial strength of the masonry element (lb, N).
- A_n = net cross-sectional area of the masonry element (in.², mm²).
- f'_m = specified compressive strength of the masonry (psi, MPa).
- h = effective height of the masonry element (in., mm).
- r = radius of gyration of the masonry element (in., mm).

For unreinforced masonry elements subjected to flexural tension, the modulus of rupture values are prescribed by the MSJC Code and vary with the direction of span, mortar type, bond pattern, and percentage of grouting, as shown in Table 28.22. For walls spanning horizontally between supports, the code conservatively assumes that masonry constructed in stack bond cannot reliably transfer flexural tension stresses across the head joints. As such, the allowable flexural tension values parallel to the bed joints (perpendicular to the head joints) for stack bond construction are assumed to be zero for design purposes.

For masonry elements subjected to a factored bending moment (M_u) and a factored axial force (P_u), the resulting flexural bending stress is determined using Equation 28.45. If the value of the bending stress (F_u) given by Equation 28.45 is positive, then the masonry section is controlled by tension, and the modulus of rupture values of Table 28.22, reduced by the appropriate strength reduction factor, must be satisfied. Conversely, if F_u as given by Equation 28.45 is negative, then the masonry section is in compression and the design compressive stress of $0.80f'_m$ applies. When using axial compressive loads to offset flexural bending stresses, only dead loads or other permanent loads should be included in P_u :

$$F_u = \frac{M_u t}{2I_n} - \frac{P_u}{A_n} \quad (28.45)$$

where:

- F_u = factored flexural stresses due to bending (psi, MPa).
- M_u = factored bending moment (in.-lb, N-mm).
- t = specified thickness of masonry element (in., mm).

TABLE 28.22 Modulus of Rupture Values, psi (kPa)

Direction of Flexural Tensile Stress and Masonry Type	Mortar Types			
	Portland Cement–Lime or Mortar Cement		Masonry Cement of Air-Entrained Portland Cement–Lime	
	M or S	N	M or S	N
<i>Normal to bed joints</i>				
Solid units	100 (689)	75 (517)	60 (413)	38 (262)
Hollow units: ^a				
UngROUTed	63 (431)	48 (331)	38 (262)	23 (158)
Fully grouted	163 (1124)	158 (1089)	153 (1055)	145 (1000)
<i>Parallel to bed joints in running bond</i>				
Solid units	200 (1379)	150 (1033)	120 (827)	75 (517)
Hollow units:				
UngROUTed and partially grouted	125 (862)	95 (655)	75 (517)	48 (331)
Fully grouted	200 (1379)	150 (1033)	120 (827)	75 (517)
<i>Parallel to bed joints in stack bond</i>	0 (0)	0 (0)	0 (0)	0 (0)

^a For partially grouted masonry, allowable stresses shall be determined on the basis of linear interpolation between fully grouted hollow units and ungrouted hollow units based on amount (percentage) of grouting.

I_n = moment of inertia of net cross-sectional area of masonry (in.⁴, mm⁴).

P_u = factored axial load (lb, N).

A_n = net cross-sectional area of masonry element (in.², mm²).

28.9.5.4.2 Shear

In-plane and out-of-plane shear stresses on unreinforced masonry elements are calculated based on the net cross-sectional properties of the masonry in the direction of the applied shear force. Because unreinforced masonry is designed to remain uncracked, it is not necessary to perform a cracked section analysis to determine the net cross-sectional area of the masonry. The nominal shear strength is taken as the smallest of the following conditions, as applicable:

$$3.8A_n(f'_m)^{0.5}$$

$$300A_n$$

For running bond masonry not grouted solid, $56A_n + 0.45N_u$

For stack bond masonry with open end units and grouted solid, $56A_n + 0.45N_u$

For running bond masonry grouted solid, $90A_n + 0.45N_u$

For stack bond masonry other than open end units grouted solid, $23A_n$

where:

N_u = factored compressive force acting normal to the shear plane that is associated with the V_u loading combination under consideration (lb, N).

A_n = net cross-sectional area of masonry element (in.², mm²).

28.9.5.5 Reinforced Masonry Design

The design of reinforced masonry in accordance with the strength design procedures of the MSJC Code neglects the tensile resistance provided by the masonry units, mortar, and grout in determining the strength of the masonry assemblage. Thus, for design purposes, the portion of masonry subject to net tensile stress is assumed to have cracked, transferring all tensile forces to the reinforcement. Strength design of reinforced masonry is based on the specified yield strength of reinforcement (f_y), which is limited to 60,000 psi (413.7 MPa). The actual yield strength of the reinforcement is limited to 1.3 times the specified yield strength. The compressive resistance of steel reinforcement is not permitted to be used unless lateral reinforcement is provided. Using strength design, reinforcing bars used in masonry are not permitted to be larger than No. 9 (M #29). Further, the nominal bar diameter is not permitted to exceed

one eighth of the nominal member thickness or one quarter of the least clear dimension of the cell, course, or collar joint in which it is placed. The area of reinforcing bars placed in a cell or in a course of hollow unit construction is not permitted to exceed 4% of the cell area.

28.9.5.5.1 Maximum Reinforcement Ratio

To provide for a prescribed level of ductility in the event of failure, the amount of reinforcement permitted in reinforced masonry construction is limited. The maximum reinforcement ratio (ρ_{\max}) is limited in accordance with Equation 28.46 or Equation 28.47, as appropriate. Equation 28.46 applies to masonry cross-sections that are fully grouted or where the neutral axis falls within the face shell of the masonry units in partially grouted construction. When the neutral axis falls within the cores of partially grouted construction, Equation 28.47 is used:

$$\rho_{\max} = \frac{0.64f'_m \left(\frac{\epsilon_{mu}}{\epsilon_{mu} + \alpha\epsilon_y} \right) - \frac{P'}{bd}}{f_y - \min \left\{ \epsilon_{mu} - \frac{d'}{d}(\epsilon_{mu} + \alpha\epsilon_y), \epsilon_y \right\} E_s} \quad (28.46)$$

$$\rho_{\max} = \frac{0.64f'_m \left(\frac{\epsilon_{mu}}{\epsilon_{mu} + \alpha\epsilon_y} \right) \left(\frac{b_w}{b} \right) + 0.8f'_m t_{fs} \left(\frac{b-b_w}{bd} \right) - \frac{P'}{bd}}{f_y} \quad (28.47)$$

where:

ρ_{\max} = maximum tensile reinforcement ratio.

ϵ_{mu} = maximum usable masonry compressive strain.

α = tension reinforcement yield strain coefficient.

ϵ_y = reinforcement strain at yield stress.

P' = axial force corresponding to load combination $D + 0.75L + 0.525Q_E$.

b = width of masonry section (in., mm).

b_w = width of the compression section minus the sum of the length of ungrouted cells (in., mm).

d = effective depth to tension reinforcement (in., mm).

d' = distance from the extreme compression fiber to the centroid of the compression reinforcement (in., mm).

f_y = nominal yield strength of reinforcement (psi, MPa).

E_s = modulus of elasticity of reinforcement (psi, MPa).

f'_m = specified compressive strength of masonry (psi, MPa).

t_{fs} = thickness of masonry face shells (in., mm).

The tension reinforcement yield strain coefficient (α) is taken as equal to 1.5 except for the following conditions:

For intermediate reinforced shear walls, $\alpha = 3.0$.

For special reinforced shear walls, $\alpha = 4.0$.

The bracketed portion of the denominator of Equation 28.46 applies when compression reinforcement is present; otherwise, this part of the expression is zero, and the denominator simply reduces to f_y . Unlike calculating nominal strengths, the compression reinforcement does not have to be laterally tied for use in Equation 28.46. This is permitted because the masonry compressive strain will always be less than the maximum permitted value. For conditions where $M_u/V_u d \leq 1$ and the masonry element is designed using a seismic response factor (R) less than or equal to 1.5, the MSJC Code does not impose an upper limit on the maximum reinforcement ratio. Similarly, when masonry shear walls are checked against the boundary element design provisions of the MSJC Code, the maximum reinforcement requirements may not apply.

28.9.5.5.2 Axial Compression and Flexure

The nominal axial strength (P_n) of masonry elements, modified to account for the effects of slenderness, is determined using Equation 28.48 or Equation 28.49, as appropriate. For masonry elements with h/r not greater than 99:

$$P_a = 0.8 \left\{ \left[0.8f'_m(A_n - A_s) + f_y A_s \right] \left[1 - \left(\frac{h}{140r} \right)^2 \right] \right\} \quad (28.48)$$

For masonry elements with h/r greater than 99:

$$P_a = 0.8 \left\{ \left[0.8f'_m(A_n - A_s) + f_y A_s \right] \left(\frac{70r}{h} \right)^2 \right\} \quad (28.49)$$

where:

- P_a = nominal axial strength of the masonry element (lb, N).
- A_n = net cross-sectional area of the masonry element (in.², mm²).
- f'_m = specified compressive strength of the masonry (psi, MPa).
- A_s = cross-sectional area of laterally tied reinforcement (in.², mm²).
- f_y = nominal yield strength of reinforcement (psi, MPa).
- h = effective height of the masonry element (in., mm).
- r = radius of gyration of the masonry element (in., mm).

The strength design method places a prescriptive cap on the axial load in accordance with Equation 28.50. Further, when the slenderness ratio (h/t) exceeds 30, the factored axial stress is limited to 5% of the specified compressive strength of the masonry ($0.05f'_m$):

$$\frac{P_u}{A_g} \leq 0.20f'_m \quad (28.50)$$

where:

- P_u = factored axial load on the masonry element (lb, N).
- A_g = gross cross-sectional area of masonry element (in.², mm²).

The nominal flexural strength (M_n) of a masonry element is determined in accordance with the following requirements. In addition, the nominal flexural strength at any section along a member shall not be less than one fourth of the maximum nominal flexural strength at the critical section. When axial loads are not present or are conservatively neglected, as may be appropriate in some cases, several circumstances must be considered when determining the nominal flexural strength of reinforced masonry walls. For a fully grouted element, the internal moment arm between the resulting compressive and tensile forces is resolved to determine the resisting capacity of the section. Partially grouted walls are analyzed in the same way but with the additional consideration of the ungrouted cores. For partially grouted masonry, two types of behavior should be considered:

- When the neutral axis (the location of zero stress) lies within the compression face shell, the wall is analyzed and designed using the procedures for a fully grouted wall.
- When the neutral axis lies within the core area, rather than the compression face shell, the portion of the ungrouted cells must be deducted from the area of masonry capable of carrying compression stresses.

The location of the neutral axis depends on the spacing of the reinforcing steel as well as the reinforcement ratio (ρ) and the distance between the reinforcement and the extreme compression fiber (d). When analyzing partially grouted walls, it is typically assumed that the neutral axis lies within the compression

face shell, as the analysis is more straightforward. Based on this assumption, the neutral axis depth (c) is calculated, where $c = 1.25a$ as determined by Equation 28.52. If it is determined that the neutral axis lies outside the compression face shell, then the more rigorous tee beam analysis is performed; otherwise, the rectangular beam analysis is carried out.

For fully grouted masonry elements and for partially grouted masonry elements with the neutral axis in the compression face shell, the nominal flexural strength (M_n) is calculated using Equation 28.51 and Equation 28.52 as follows:

$$M_n = (A_s f_y + P_u) \left(d - \frac{a}{2} \right) \quad (28.51)$$

$$a = \frac{P_u + A_s f_y}{0.8 f'_m b} \quad (28.52)$$

where:

M_n = nominal moment strength of the masonry element (in.-lb, N-mm).

A_s = cross-sectional area of tension reinforcement (in.², mm²).

f_y = nominal yield strength of tension reinforcement (psi, MPa).

P_u = factored axial load on the masonry element (lb, N).

d = effective depth to tension reinforcement (in., mm).

a = depth of equivalent compression zone (in., mm).

f'_m = specified compressive strength of the masonry (psi, MPa).

b = width of the masonry section under consideration (in., mm).

Conversely, for partially grouted masonry walls where the neutral axis is located within the cores, the nominal flexural strength (M_n) is calculated using Equation 28.53, Equation 28.54, and Equation 28.55 as follows:

$$M_n = (A_s f_y + P_u)(d - X) \quad (28.53)$$

$$X = \frac{\frac{b(t_{fs}^2)}{2} + b_w(a - t_{fs}) \left(t_{fs} + \frac{a - t_{fs}}{2} \right)}{b t_{fs} + b_w(a - t_{fs})} \quad (28.54)$$

$$a = \frac{P_u + A_s f_y}{0.8 f'_m b_w} - t_{fs} \left(\frac{b}{b_w} - 1 \right) \quad (28.55)$$

where:

b_w = width of the compression section minus the sum of the length of ungrouted cells (in., mm).

t_{fs} = thickness of the masonry face shells (in., mm).

To account for deflection resulting from the application of out-of-plane loads and the additional bending moment due to eccentrically applied axial loads, the factored bending moment at the mid-height of a simply supported wall under uniform loading is required to be determined by Equation 28.56. When other support or loading conditions exist, appropriate design models should be used instead of Equation 28.56. The deflection due to factored loads (δ_u) is determined using Equation 28.58 or Equation 28.59 by replacing M_{ser} with M_u :

$$M_u = \frac{w_u h^2}{8} + P_{uf} \frac{e_u}{2} + P_u \delta_u \quad (28.56)$$

where:

M_u = factored bending moment (in.-lb, N-mm).

w_u = factored out-of-plane uniformly distributed load (lb/in., N/mm).

- h = effective height of the masonry element (in., mm).
 e_u = eccentricity of P_{uf} (in., mm).
 δ_u = deflection due to factored loads (in., mm).
 $P_u = P_{uw} + P_{uf}$.
 P_{uf} = factored load from tributary floor or roof areas (lb, N).
 P_{uw} = factored weight of masonry element area tributary to section under consideration (lb, N).

The strength design method also includes a deflection check using unfactored service loads to satisfy Equation 28.57:

$$\delta_s = 0.007h \quad (28.57)$$

The mid-height deflection of a simply supported masonry element can be calculated using either Equation 28.58 or Equation 28.59, as appropriate. P-delta effects should be included in the deflection calculation. The cracking moment strength of the element (M_{cr}) is determined using the modulus of rupture values in Table 28.22:

Where $M_{ser} < M_{cr}$:

$$\delta_s = \frac{5M_{ser}h^2}{48E_mI_g} \quad (28.58)$$

Where $M_{cr} < M_{ser} < M_n$:

$$\delta_s = \frac{5M_{cr}h^2}{48E_mI_g} + \frac{5(M_{ser} - M_{cr})h^2}{48E_mI_{cr}} \quad (28.59)$$

where:

- δ_s = deflection at mid-height under service level loads (in., mm).
 h = effective height of the masonry element (in., mm).
 M_{ser} = mid-height bending moment including P-delta effects under service level loads (in.-lb, N-mm).
 M_{cr} = nominal cracking moment strength (in.-lb, N-mm).
 E_m = modulus of elasticity of masonry (psi, MPa).
 I_g = moment of inertia of gross cross-sectional area of masonry element (in.⁴, mm⁴).
 I_{cr} = moment of inertia of cracked cross-sectional area of masonry element (in.⁴, mm⁴).

28.9.5.5.3 Shear

Unlike allowable stress design, shear acting on reinforced masonry members design by the strength design method is resisted by the masonry and shear reinforcement, if provided, in accordance with Equation 28.60:

$$V_n = V_m + V_s \quad (28.60)$$

where V_n is not permitted to exceed the value calculated using either Equation 28.61 or Equation 28.62, as appropriate. For values of $M_u/V_u d_v$ between 0.25 and 1.0, the maximum value of V_n is permitted to be linearly interpolated.

Where $M_u/V_u d_v \leq 0.25$:

$$V_n \leq 6A_n \sqrt{f'_m} \quad (28.61)$$

Where $M_u/V_u d_v \geq 1.0$:

$$V_n \leq 4A_n \sqrt{f'_m} \quad (28.62)$$

The nominal shear strength provided by the masonry (V_m) in Equation 28.63 is determined in accordance with Equation 28.62:

$$V_m = \left[4.0 - 1.75 \left(\frac{M_u}{V_u d_v} \right) \right] A_N \sqrt{f'_m} + 0.25 P_u \quad (28.63)$$

The value of $M_u/V_u d_v$ in Equation 28.63 need not be taken greater than 1.0 but is required be taken as a positive number.

The nominal shear strength provided by the shear reinforcement (V_s) is determined by Equation 28.64:

$$V_s = 0.5 \left(\frac{A_v}{s} \right) f_y d_v \quad (28.64)$$

where:

- V_n = nominal shear strength (lb, N).
- V_m = nominal shear strength provided by the masonry (lb, N).
- V_s = nominal shear strength provided by shear reinforcement (lb, N).
- A_n = net cross-sectional area of the shear plane (in.², mm²).
- f'_m = specified compressive strength of the masonry (psi, MPa).
- M_u = factored bending moment (in.-lb, N-mm).
- V_u = factored shear force (lb, N).
- d_v = depth of masonry in the direction of the shear force (in., mm).
- P_u = factored axial load on the masonry element (lb, N).
- A_v = cross-sectional area of shear reinforcement (in.², mm²).
- s = spacing of shear reinforcement (in., mm).
- f_y = nominal yield strength of shear reinforcement (psi, MPa).

28.10 Summary

Although versatile in its application, the limitless array of possibilities offered by masonry construction also presents unique challenges that, when not properly accounted for in design and construction, can lead to problematic circumstances in the future. Throughout this chapter, emphasis has been given to some of the aspects not usually covered in conventional design and construction handbooks. When these practices and recommendations are combined with standardized design and construction provisions for masonry, however, the successful use of masonry in future projects is ensured. The discussion presented in this chapter is intended to provide the user with a general overview of the basic considerations related to masonry materials, their construction, and their governing design requirements. The references listed at the end of the chapter provide a more detailed discussion and review of this topic and should be referred to as necessary.

Acknowledgment

The author would like to acknowledge with thanks the extensive contributions of the late Walter L. Dickey for his groundbreaking advances in the art and science of masonry design and construction as well as his admirable work in writing with M. J. Dickey the earlier edition of this chapter.

29.1 Aesthetics in Concrete Bridges

29.1.1 Introduction

Many important factors collectively contribute to the aesthetic appeal of a bridge. Both the design and construction play key roles in achieving aesthetic qualities. This chapter explores various topics regarding the development of aesthetically pleasing, long-span prestressed concrete bridges. The focus for long

* President/Director of Bridge Art, FIGG, Tallahassee, Florida; expert in aesthetic design and construction of concrete segmental bridges.

spans is on the use of concrete segmental box girders to achieve sizeable spans and versatility of form. Bridge design and construction represent more than simply providing a transportation link between two points. Communities want bridges that are visually pleasing, reflective of their place, and sensitive to the environment. Additionally, the public wants construction projects to be completed quickly and to minimize disturbance to the already congested traffic. These increased expectations are combined with public agencies' need for economical construction due to limited funding. Designers and builders are responding to these needs and desires by becoming more innovative in their approach to bridge design and construction. Aesthetics, economy, environmental sensitivity, and sustainability are being combined with function and constructability to provide new bridges that satisfy these expectations.

29.1.2 Bridge Aesthetics

Bridge aesthetics are born out of design efficiency and sensitivity to visually pleasing details. Bridges are created with a sizeable investment of funds with the idea that a new landmark bridge will stand the test of time physically as well as visually. The bridge leaves an impression, and that impression remains for as long as the bridge remains, so bridge designers owe it to the community to create something that is beautiful. The first step is to solve the technical challenges. Many important decisions are involved in creating an economical solution, and the initial decisions form the framework of structural efficiency that ultimately leads to the final aesthetic opportunity, with the remainder of the details building upon the initial functional solution. With a concentrated effort on efficient design and construction, the bridge aesthetics can be achieved within the context of the expected construction costs and often at a cost savings.

29.1.3 Signature Design

By approaching bridge design as creating a work of art, a signature design is born. The value of bridge aesthetics is found in the iconographic power that translates into economic development and sustainability within the landscape and context of the site. Each bridge site is unique. Similar design approaches may be utilized, but to create a landmark everything unique to that location must be explored and embraced to create a one-of-a kind signature design that becomes a community landmark.

29.1.4 Definition of Design Principles

Aesthetically pleasing bridge design has four basic requirements:

- It must be functional.
- It must be economical.
- It must be culturally satisfying to the community.
- It must exist in harmony with the environment.

Design principles that guide a designer's attempts to satisfy these requirements include establishing a theme, blending shapes, creating shadows, using appropriate textures and colors, and incorporating native materials and feature lighting. Establishing a theme reflective of the local community is a unifying element for all bridge components. The bridge alignment and shapes combine to form the overall aesthetic appeal of a bridge. The shape and contours of the bridge create shadows that provide depth and varying expressions as the natural light evolves throughout the day. Color, texture, and the use of native materials further enhance the visual interest of the bridge structure. A nighttime signature may be created through the use of aesthetic lighting. Other design details, such as appropriate landscaping, can create a seamless connection between the bridge and the site.

Examples of bridges that have achieved exceptional aesthetics, as judged by numerous award juries, are the I-275 Bob Graham Sunshine Skyway Bridge in Tampa, Florida (Figure 29.1); the Natchez Trace Parkway Arches near Nashville, Tennessee (Figure 29.2); and the Blue Ridge Parkway Viaduct around Grandfather Mountain, North Carolina (Figure 29.3). All three were selected by the National Endowment for the Arts to receive the coveted Presidential Design Award.

FIGURE 29.1 Bob Graham Sunshine Skyway Bridge has a 1200-ft main span and carries I-275 across Tampa Bay, Florida; the bridge was the recipient of the 1988 Presidential Design Award.

FIGURE 29.2 Natchez Trace Parkway Arches has a 582-ft main span and is located outside of Nashville near Franklin, Tennessee; the bridge was awarded the 1995 Presidential Design Award.

FIGURE 29.3 The Blue Ridge Parkway Viaduct has 180-ft spans and wraps around Grandfather Mountain in North Carolina; the viaduct was the recipient of the 1984 Presidential Design Award.

FIGURE 29.4 The Natchez Trace Parkway Arches bridge demonstrates efficient design resulting in economical construction.

29.2 Conceptual Design

The conceptual design phase of a bridge project provides the necessary groundwork for the best aesthetic opportunity. The overall alignment and geometry are established at this time, in addition to determining span lengths and the structural depth and dimensioning of superstructure and substructure elements. These project elements are determined based on an analysis of the site and determination of the most appropriate bridge type to create both a functional and a visually pleasing bridge. The conceptual design must call on engineering judgment and an understanding of how to best optimize construction to properly balance economy, functionality, and lasting visual quality. Experience has shown that superior bridge aesthetics can be achieved at reasonable construction costs, and, in fact, efficient designs can result in costs savings. Aesthetic form follows well-designed function. An example of this is the Natchez Trace Parkway Arches project (Figure 29.4), which was completed for \$11.3 million in 1993. The functional requirement of spanning the valley resulted in a long-span arch structure with a 582-ft span. To develop a modern and open design, the vertical spandrels typically seen in traditional arches were removed, resulting in the superstructure load being translated to the arch at one expanded platform at the top. Traditional methods of precast balanced cantilever construction were used for the superstructure. The arch itself was comprised of precast segments built in a cantilever fashion from the foundations using cable supporting technology until the arch was connected in the center. By addressing components of the bridge separately and yet together, a total system can be developed founded on known methods of construction and creating a unique design (Figure 29.5).

Efficiency, as well as pleasing aesthetics, may be achieved through consistency in design elements and shapes. A uniform appearance among the bridge elements is important and may be accomplished through consistency in form, line, and pattern. The lines of a structure draw a viewer's eye from one form to another which, when done well, creates visual continuity. One way to achieve this is by using the same superstructure cross-section for the full length of the bridge. Two primary benefits emerge: a more aesthetically pleasing appearance and increased efficiency during construction due to the repetition of form. An example of this approach is the Chesapeake and Delaware Canal Bridge near St. Georges, Delaware (Figure 29.6). The superstructure was designed such that the same cross-section shape could

FIGURE 29.5 During construction, proven construction techniques combine to create a unique design.

be used for the 150-ft approach spans as well as the 750-ft cable-stayed main span. To create the cable-stayed main span, a precast delta frame was introduced to tie the two superstructure box girders together and house the cable stay anchorages below the deck level. The economical benefits were demonstrated by the low bid of \$59 million that was within budget and \$6 million less than the alternative design.

29.2.1 Alignment

Generally, bridge alignments are influenced by existing roadway networks, although some opportunities arise when new transportation corridors are created. Whether the bridge is a replacement structure, parallel structure, or new structure, it must fit within the roadway system. The specific alignment

FIGURE 29.6 The Chesapeake and Delaware Canal Bridge in Delaware uses repetition of form and construction.

determined for the bridge will consider grades and elevations of existing and proposed roads, the terrain it will traverse, and what features the structure crosses, such as bodies of water, roadways, railroads, or other existing and proposed site constraints. Bridge alignment has the first and most profound effect on the overall approach to the bridge design and aesthetics. The length of the structure, especially the length of the visually dominant main span, will dictate the type of structure and method of construction that are most suitable. Alignment and location of the bridge will affect many aspects of construction such as how materials are delivered, whether erection will take place over traffic or over an active navigational channel, or if environmentally sensitive areas will require another level of special care. These and all aspects of construction must be considered during alignment determination.

29.2.2 Span Length

In addition to the overall bridge length, the individual span lengths of a bridge are based on the alignment, existing site constraints, and potential construction methods. Span lengths are determined after the overall length and alignment have been established and existing site constraints identified. Unit configurations are also established to create a continuous structure of several spans to reduce the number of expansion joints. The various combinations of construction methods, span lengths, and unit configurations are evaluated to determine the most feasible alternative; for example, when establishing span lengths for concrete balanced-cantilever construction, side span lengths should be set at 60% of the main span length. The Smart Road Bridge (Figure 29.7) near Blacksburg, Virginia, is a 1984-ft-long bridge of one continuous unit that consists of three interior spans of 472 ft each with side spans of 284 ft. The goal in establishing the span length is to determine the optimal span length and consistently utilize this length throughout the project, as much as possible. This will increase the efficiency of the project by introducing repetition into the construction operations, resulting in economical construction costs. The balanced and repetitive span lengths also provide continuity in appearance, resulting in visually appealing structures. Span length, in concert with structure depth, is the single most important aspect of establishing the aesthetic quality of a bridge; it sets the stage for the overall appearance of the structure and how it flows into its visual environment.

FIGURE 29.7 The long spans of Virginia's Smart Road Bridge provide for open views of the valley; the bridge was built via balanced cantilever construction.

FIGURE 29.8 Four Bears Bridge in rural North Dakota has a variable depth superstructure for 316-ft spans following a uniform pattern for construction efficiency.

29.2.3 Structural Depth

Many variables go into determining structural depth. Typically, maintaining a constant box girder depth, as well as a constant cross-section, will greatly simplify casting and erection operations, thus reducing construction costs. To determine the appropriate structure depth, the bridge engineer must evaluate all spans and units to determine the governing conditions and minimum structural depth required. This is accomplished in combination with addressing the required vertical clearances. For longer span bridges, however, it is often more economical to vary the depth of the superstructure instead of maintaining a constant depth. A deeper box girder section is required to resist the higher forces closer to the piers, while at midspan a shallower section is adequate to resist the lower forces. The structural depth, therefore, is often gradually decreased over the length of the span to minimize quantities and to reduce the weight of the structure. This can be achieved with graceful, sweeping curves that will enhance the visual appeal of the structure by making it appear more slender and elegant. An example of this is the Four Bears Bridge (Figure 29.8) near New Town, North Dakota, which has 316-ft spans and a variable superstructure depth ranging from 16 ft, 7 in. at the piers to 7 ft, 7 in. at midspan.

29.2.4 Span-to-Depth Ratio

Determining an ideal span-to-depth ratio is an essential factor in the overall aesthetic appearance of the structure. It influences the visual impact of the structure within the surrounding landscape. Many options exist that can optimize the structural efficiency of the superstructure box girder cross-section while creating an elegant structure. Creating the most aesthetically pleasing combination of span length and superstructure depth is often an iterative process. Based on experience, span-to-depth ratios ranging from 20 to 30 will result in superior aesthetics. A span-to-depth ratio of 15 on uniform spans is also considered visually appealing, but less than 15 is not preferable. The Victory Bridge (Figure 29.9) in New Jersey incorporates a 440-ft precast segmental main span with a variable-depth superstructure. The span depth varies from 21 ft at the main piers to 10 ft at the center span, resulting in a span-to-depth ratio of 22. The 150-ft

FIGURE 29.9 A high span-to-depth ratio results in structures that have elegant proportions. The Victory Bridge (440-ft main span) over the Raritan River in New Jersey serves as an excellent example.

approach spans have a constant depth of 9 ft, resulting in a span-to-depth ratio of 15. Long-span girder bridges present interesting opportunities. As noted in Section 29.2.3, as the span increases, the magnitude of the forces near the piers normally requires variation in structural height. When clearance requirements allow, a circular variation in structure depth is more aesthetically pleasing than a linearly varying structure depth. An example of such an approach is the Wabasha Freedom Bridge (Figure 29.10) in St. Paul, Minnesota. This bridge has a 400-ft span with a 20-ft-deep section at the pier and an 8-ft-deep section at midspan, resulting in a span-to-depth ration of 20 and a gradually varying, long sweeping curve.

FIGURE 29.10 The Wabasha Freedom Bridge in St. Paul, Minnesota, achieves a span-to-depth ratio of 20 and demonstrates that varying the depth of the superstructure creates pleasing shapes.

FIGURE 29.11 North Carolina's Blue Ridge Parkway Viaduct was built from the top to protect the sensitive environment so the mountain's owner would allow construction of this important link.

29.3 Environmental Sensitivity

29.3.1 Protecting the Natural Environment

Innovative methods of construction have been developed to protect the natural environment while providing necessary transportation infrastructure. A section of the Blue Ridge Parkway around Grandfather Mountain in North Carolina (Figure 29.11) challenged engineers for years due to the environmentally sensitive ecology of the area. This obstacle was overcome by erecting a precast concrete segmental bridge utilizing top-down construction. Starting at the abutment, the eight-span continuous viaduct was built in a unidirectional progressive cantilever (Figure 29.12). The segments were delivered by truck over

FIGURE 29.12 A progressive unidirectional cantilever, from above, protected the mountain during construction.

FIGURE 29.13 Protecting Glenwood Canyon in Colorado was a top priority during the design and construction of its first five bridges.

the completed structure as it advanced and was progressively post-tensioned in place. Other challenges that had to be overcome included the rugged terrain, being 4400 ft above sea level, and the unusually complex alignment geometry with tight horizontal curves that reverse direction. The piers were also constructed from the top down by constructing the cantilever toward the next pier and then reaching out and down to construct the pier with precast segments. The precast pier segments were then delivered across the completed deck to the edge of the cantilever span, lowered into position, and vertically post-tensioned in place.

The Glenwood Canyon Bridges (Figure 29.13) along Interstate 70 west of Denver, Colorado, are other examples of structures built in an environmentally sensitive area. Five bridges demanded an innovative approach in design and construction to meet the environmental restrictions in the terrain of the canyon. With the Colorado River on one side and mountain cliffs on the other, the construction was confined. A precast concrete segmental bridge was designed for the location, with the precast box girders being trucked to the erection site and delivered over the completed bridge deck. Temporary erection trusses were used to support the segments in each span during construction until the longitudinal post-tensioning could be stressed to make the spans self-supporting. The trusses were temporarily supported from the permanent piers, thus eliminating the need for falsework, which would have damaged the existing landscape. Once a span was completed, the trusses were launched forward to the next span location from above, avoiding impact to the sensitive ground below. These two projects are examples of what may be accomplished with existing, proven construction techniques. Preserving the environment and enhancing the natural landscape are outcomes of thoughtfully evaluating the bridge design and construction methods during the conceptual design stage.

29.3.2 Context-Sensitive Design

Construction of a bridge should preserve and protect the existing environment and visually complement the site. Designing bridges that reflect the environment and the spirit of the communities they serve generates community pride and results in a bridge that becomes a timeless landmark and a legacy left to future generations. The Four Bears Bridge near New Town, North Dakota, spans Lake Sakakawea on the Fort Berthold Indian Reservation. This award-winning bridge was designed using the Federal Highway Administration's (FHWA) Context-Sensitive Design (CSD) process, defined as "a collaborative, interdisciplinary approach that involves all stakeholders to develop a transportation facility that fits its physical setting and preserves scenic, aesthetic, historic, and environmental resources, while maintaining safety and mobility. CSD is an approach that considers the total context within which a transportation improvement

project will exist.” For the Four Bears Bridge, CSD was accomplished through regular meetings between the North Dakota Department of Transportation (NDDOT), the design team, the Three Affiliated Tribes (TAT), and the six communities that comprise the Fort Berthold Indian Reservation. Details of the project were presented to members of the TAT, and volunteers were solicited to form a Cultural Advisory Committee (CAC) to bring Native American guidance to the CSD process. The initial purpose of the CAC was to develop a project theme. Other project components were determined through a 2-day FIGG Bridge Design Charette™ (public workshop) to further implement CSD. The design charette provided stakeholders with a formal decision-making process that considered their preferences and allowed prioritization of the following bridge elements: roadway lighting, aesthetic lighting, pier shapes, traffic railing, pedestrian railing, bridge profiles, sidewalk linear library, bridge end treatments, and bridge color and textures. The result is a celebrated, aesthetically pleasing structure that is in context with its environment and a source of pride for the surrounding communities.

29.4 Construction Methods

Concrete segmental bridges for long spans are typically erected using the span-by-span or balanced cantilever construction methods. Determining the method of construction and bridge type requires taking into consideration the required span length and the existing site constraints, such as environmental restrictions, existing traffic, bodies of water, or limited right of way. The owner’s required schedule may also dictate one method over the other, while the contractor’s equipment or the size of project may also be determining factors. The advantages and disadvantages of various approaches must be analyzed early in the conceptual design phase to determine the best one. For particularly large or complex projects, both span-by-span and balanced cantilever methods may be utilized. This may speed construction by allowing the simultaneous erection of spans at different locations of the project. Construction of the Victory Bridge in northern New Jersey, for example, was accomplished by erecting the approach spans with span-by-span construction while simultaneously erecting the main span using balanced cantilever construction (Figure 29.14). This expedited the construction schedule, which was a major goal of the

FIGURE 29.14 Span-by-span erection of the approach spans expedited completion of New Jersey’s Victory Bridge.

FIGURE 29.15 AirTrain JFK, the light rail system around New York's JFK Airport, was erected utilizing both span-by-span and balanced cantilever construction methods to achieve an aggressive schedule.

New Jersey Department of Transportation. For the superstructure of AirTrain JFK (Figure 29.15), both methods were employed. Span-by-span was used primarily to speed up the process, and balanced cantilever construction was applied to a small number of longer spans and spans with tight horizontal curvature. Both the span-by-span and balanced cantilever construction methods have been used successfully in the industry and are customary; however, advances in technology and equipment continue to be made. For all projects, a contractor may opt to use unique means and methods that may differ from the assumptions made by the design engineer during the design phase. In these circumstances, further construction analysis is required to verify the design under the revised construction loadings. A description of span-by-span construction follows. A detailed description of balanced cantilever construction, for both cast-in-place and precast concrete, can be found elsewhere in this book.

29.4.1 Span-by-Span

The span-by-span method of construction was developed to construct long bridges with repetitive span lengths, with construction taking place at deck level without the use of extensive falsework. It is typically accomplished using a truss or pair of trusses supported by the bridge piers. Segments are delivered to the site and placed on the erection truss. A winch brings the segments to their final location. When all segments are in place, temporary blocking is placed across the closure joints, and a nominal prestress force is applied to ensure tight fit of all the precast segments. Closure joint concrete is poured, longitudinal duct work secured, and post-tensioning tendons threaded and stressed. The construction cycle is completed when the assembly trusses are advanced to the next span. This is a quick and efficient method of construction for precast concrete segmental bridges and is ideal for straight or curved bridges. It requires less prestressing steel than balanced cantilever construction because no cantilever stresses occur during construction.

Precasting offers the advantage of the simultaneous casting of segments off-site, while the foundations and piers are constructed on-site. A casting yard may be established in close proximity or where land and easy access for segment delivery are available. Segments are cast in controlled, factory-like conditions that produce high-quality products and consistent results for material strength, geometry control, and rebar placement. When the concrete has been satisfactorily cured and ready for erection, segments may

be delivered from the casting yard to the project site by barge, truck, or segment haulers, depending on the contractor's equipment and the proximity of the casting yard to the project site. Pier segments can also be precast and delivered in the same manner. Depending on site constraints (limited right of way, traffic maintenance, or environmental restrictions) and contractor equipment, segment delivery and placement on the truss may be accomplished in several different ways. If construction is limited to top down, trucks can deliver segments over the newly completed structure that are then placed on the truss with a crane that moves along the progressively completed superstructure. Where at-grade access is permitted, a ground-based crane can pick segments from delivery at-grade and place them on the truss. Barge-mounted cranes may be utilized if the bridge is over navigable water.

29.4.2 Cable-Stayed Bridges

Long spans may be accomplished economically with a cable-stayed bridge design and may be either precast or cast in place. The length and depth of the span determine the number and size of pylons and cables, as well as the geometric configuration of the cables and segment lengths. In this type of construction, the preferred length of the back spans is half the length of the main span. In some situations, however, this is not possible due to existing conditions, geometry, or other site constraints. This results in asymmetrical designs that require compensation for the unequal span lengths by providing additional superstructure weight to balance the spans or by using other creative engineering solutions.

Precast segmental cable-stayed construction is a special subset of precast cantilever construction. The Chesapeake and Delaware Canal Bridge in Delaware has a 750-ft main span that was built via unidirectional cantilever using permanent cable stays and precast delta frames (Figure 29.16). The single plane

FIGURE 29.16 Precast delta frames between the parallel box girders transfer forces from the superstructure to the cable stays.

of 16 cable stays at each pylon supports the main span, creating a graceful appearance that blends the structure into the landscape. The pylons were cast in place in 10-ft lifts with cable stays initiating at the third lift above the roadway. The saddle cable stay pipe that runs through the pylon transfers the forces from the stays down through the pylon and into the main pier foundation. The cable stays anchor in the precast delta frames at the deck level spaced at 20-ft intervals. The delta frames transfer loads from the roadway segments to the cable stay system, allowing the same cross-sectional shape of the box girders to be used in both the approach spans and the main span. The delta frames also connect the twin parallel trapezoidal box girders of the main span into a single rigid cross-section. The approach spans were built using span-by-span construction prior to erection of the main span which allowed the delivery of main-span segments over the newly constructed back spans. This, in conjunction with the use of crawler cranes on both sides of the canal, allowed erection of the center span from above, with minimal disruption to the navigational traffic in the canal. The main span was erected in cycles: erection of four precast segments, erection of a precast delta frame, installation and stressing of a cable stay.

The Penobscot Narrows Bridge and Observatory (Figure 29.17) is the first cable-stayed bridge in Maine and was built using the balanced cantilever method with cast-in-place form travelers. Form travelers are forms that advance by a rail assembly that is affixed to the deck during construction. In this case, from

FIGURE 29.17 Form travelers on the cantilever tips were used to cast the superstructure in place for Maine's Penobscot Narrows Bridge and Observatory.

each of the pylons a back-span segment was cast, then a main-span segment, following a typical construction cycle of launching the traveler into position; prealigning the formwork; placing post-tensioning hardware, reinforcement, and precast struts; performing final alignment of formwork; casting the segment; performing a morning as-cast survey to verify geometry; stressing applicable post-tensioning; stripping formwork; and launching the traveler into position to cast the next segment. Traditionally, cable-stay strands have been stressed with large jacks that tension all strands simultaneously. On this bridge a different approach was used to stress the cable stays. To work within the interior of the cast-in-place box, monostrand stressing was used, where the strands were stressed one at a time. This requires a significantly smaller and more portable jack and an analysis of the different strand patterns to determine the appropriate sequence for strand stressing.

29.4.3 Urban Environments

Meeting the transportation demands of providing greater roadway capacities within restricted urban corridors requires specially tailored solutions. Some of the most challenging expansion situations may be solved by building up within the existing right of way, instead of out with more lanes at-grade. Building within the existing medians and shoulders eliminates the high expense and difficult task of obtaining new right of ways from major commercial and residential properties to expand facilities at-grade. The use of concrete segmental box girders allows for slender pier shapes and a small groundline footprint, thus maximizing the available space within the existing corridor. Another benefit of this solution is that when additional capacity is added over existing at-grade traffic signalized intersections are maintained and traffic above moves uninterrupted. This removes through traffic from the at-grade facility, reducing congestion and allowing the local at-grade traffic to reach their destinations more easily.

One example of this approach is the elevated toll road that was constructed within the median of the existing Lee Roy Selmon Crosstown Expressway (also known as State Road 618) in Tampa, Florida (Figure 29.18). To add the necessary capacity to the existing four-lane, divided, limited-access toll road without expanding the footprint of the highway, the Tampa–Hillsborough Expressway Authority developed an

FIGURE 29.18 Utilizing the existing median for an elevated structure solved commuter congestion in Tampa, Florida. Piers use 6 ft of space in the median to carry three lanes of traffic above.

FIGURE 29.19 Span-by-span erection was completed in the median of the Van Wyck Expressway, where over 160,000 vehicles pass each day.

innovative vision of an elevated structure to carry reversible express lanes. Traffic congestion is highly directional, as 80% of the morning traffic is westbound into Tampa, and 75% of the evening traffic is eastbound, headed out of the city. Reversible lanes were seen as an efficient means of providing the additional capacity when and where it was needed most. This innovative structure provides the capacity of six vehicle lanes within the 6-ft footprint of the piers. This structure was constructed while existing traffic remained in operation and was accomplished within the existing right of way.

A 2.3-mile section of the AirTrain JFK, the light-rail system for the JFK Airport, was built in the existing median of New York City's Van Wyck Expressway, an extremely congested six-lane highway closely bordered by residential and commercial properties (Figure 29.19). The erection methods and four erection trusses allowed construction to proceed with minimal disruption to traffic. An average of 2.5 spans 125 ft long were completed weekly within the median. At 7 ft, 8 in., the bases of the piers creatively utilize the space provided by the 10-ft median.

Interstate 110 in Biloxi, Mississippi, incorporated both span-by-span and balanced cantilever construction for its bridges so it could thread its way through the urban environment and over traffic (Figure 29.20). The interstate runs through a developed urban area, wraps around existing buildings, and maintains the integrity of established neighborhoods. This was accomplished by utilizing construction

FIGURE 29.20 Interstate 110 runs through downtown Biloxi, Mississippi, on an elevated structure.

systems that did not interfere with day-to-day traffic flow to provide aesthetically pleasing bridges. Using precast concrete segmental construction and slim piers, the bridges were built in existing or limited rights of way and over U.S. 90, a major tourist route that follows the Gulf Coast shoreline.

29.5 Concrete Bridge Shapes for Construction

When designed appropriately, the overall bridge form, superstructure, and substructure shapes connect seamlessly. They are in harmony with each other, and the eye flows naturally across the structure and its landscape. When forming the final sculptured shapes of bridge elements, it is important to fully consider how the shapes will integrate into the overall visual experience by taking into account the following: how light will interact with the structure, whether or not aesthetic lighting is going to be included in the project, the appropriate use of color and texture for the location, who will view the bridge, and from what vantage points the bridge be seen. Determining the final aesthetic details in the shaping of the superstructure and piers will create lines, patterns, and shadowing effects that can more completely convey the theme of the structure and be a sustainable design for the context of the site.

29.5.1 Superstructure Shape

The basic overall dimensions of the superstructure are based on structural requirements. For the 17th Street Bridge in Fort Lauderdale, Florida (Figure 29.21), the precast concrete segmental approaches to the bascule main span consist of a closed box shape with sloping vertical webs. The shaping of a closed box girder was selected for its inherent visual appeal, derived from the smooth surfaces of continuous flat planes, while the cantilever wings at the top of the box section provide openness underneath and pleasing shadow effects. There are long spans over land on both sides of the river connecting to the main span crossing the Intracoastal Waterway. Additional landscaping, aesthetic lighting, and hardscape elements beneath these land spans have created new public gathering places. The sculptural shapes of the bridge and the smooth underside enhance these new parks and green spaces. Angular lines comprise the superstructure cross-section of the Interstate 76 Susquehanna River Bridge near Harrisburg, Pennsylvania (see Figure 29.25). The simple, crisp lines add to the overall aesthetic appeal of the structure. At night, web-wall wash lighting, seemingly hidden within the lobe beneath the barrier rail, enhances the smooth web walls. The superstructure cross-section of the Lee Roy Selmon Crosstown Expressway Expansion in Tampa, Florida (Figure 29.22), contains curves in the webs and on the bottom soffit of the box that contribute to its distinctive appearance. The curves and long cantilever wings in combination with the height of the piers give the superstructure a slender appearance with shadowing. The curved lobes at the

FIGURE 29.21 Clean lines and smooth undersides of the box girder superstructure enhance Fort Lauderdale's 17th Street Bridge approaches, which largely cross over land.

FIGURE 29.22 The unique box shape of Tampa's Lee Roy Selmon Crosstown Expressway Expansion was an economical answer to achieving aesthetic goals.

FIGURE 29.23 Subtly shaped piers carry Interstates 10 and 35 in San Antonio, Texas.

corners of the soffit hide the bearings so the superstructure appears to have a seamless connection with the piers. This unique shaping creates an elegant, sculpted structure. From a constructability perspective, the overall cross-section shape remains the same throughout the bridge length to maximize the repetition of casting and to allow the casting cells to be constant. Variable bridge deck widths were accommodated by lengthening the cantilever wings as the bridge deck widens. This focus on constructability allowed the bridge to be economically constructed with a special one-of-a-kind superstructure shape.

29.5.2 Pier Shape

The pier shape is another opportunity for a designer to distinguish the aesthetics and visual appeal of the structure. The shape of the piers and their transition into the superstructure are key design features that create interesting lines and shadows. Slender piers that have a relatively high height-to-width ratio and taper at the top provide a graceful connection with the superstructure. An example is the pier shape used on the San Antonio “Y” bridges that carry Interstates 10 and 35 in downtown San Antonio, Texas (Figure 29.23).

In addition to satisfying the project design criteria, the overall cross-sectional shape of the pier should be considered in light of how the pier relates to the superstructure shape and size, the context of its environment, and the theme of the project. Simple shapes, such as an elliptical shape (Figure 29.24), can provide a classic look. An elliptical shape, while visually pleasing, also provides the benefit of reducing the drag coefficient of hurricane wind conditions such as in the case of the Bob Graham Sunshine Skyway Bridge that carries Interstate 275 across Tampa Bay, Florida (see Figure 29.1). The twin elliptically shaped piers used for the main span contribute to the overall aesthetic appeal of the bridge, but the shape was primarily chosen because it best fulfills the design requirements for the bridge to be able to sustain hurricane-force winds.

Main piers for long-span designs built in balanced cantilever are designed to provide structural stability of the cantilevers during construction, as well as providing structural capacity under final service loads. Often, unbalanced construction loads and wind loads, including hurricane winds, can require sizable main piers; however, a functional and aesthetic solution can be developed with the use of twin walls. Twin-wall, cast-in-place piers on the Wabasha Freedom Bridge in St. Paul, Minnesota (see Figure 29.10), not only provide visual appeal but also were designed to help counter the unbalanced loads on the foundations during balanced cantilever construction. The piers provided longitudinal flexibility combined with stability for cantilever erection. The piers are integrated into the superstructure with reliefs that reflect an Art Deco architectural style. The reliefs cast into the pier and the detailing at the super-

FIGURE 29.24 Elliptical pier shapes add aesthetics while reducing wind drag, an important consideration in hurricane-prone areas (I-275 Bob Graham Sunshine Skyway Bridge).

structure hide the bearings at the interface. This style was also adopted for the details of stairways, overlooks, walls, paths, and other features in the landscaped park areas to tie the entire project together.

In those situations where it is possible to eliminate bearings, a monolithic connection between the pier and the superstructure may add to the aesthetics of the bridge. At the Smart Road Bridge near Blacksburg, Virginia (see Figure 29.7), the pier faces continue vertically to intersect with the superstructure web wall, creating a fixed or monolithic connection between the piers and the superstructure. This approach eliminated the need for bearings at the piers and adds an aesthetic feature to the elevation of the bridge. In rugged environments, angular shapes blend in naturally with the mountainous terrain. An octagonal-shaped pier was used to blend the Blue Ridge Parkway Viaduct into the rocky outcroppings of Grandfather Mountain, North Carolina (see Figure 29.3 and Figure 29.11).

Visual interest may be created by the use of simple-cross sectional shapes in a cost-efficient manner. Vertical articulations may be cast into a pier recess, producing a slender appearance through shadows. Vertical lines created by casting a pier inset or by the cross-sectional shape itself may visually add to the height of a shorter pier and create visual interest for those viewing the piers from below. At the Interstate 76 Susquehanna River Bridge (Figure 29.25), a stone pattern provides texture on the piers, reflecting the stone on the nearby Pennsylvania Turnpike Commission building.

FIGURE 29.25 A stone pattern texture was used on the piers of Pennsylvania’s Susquehanna River Bridge to create a linear accent.

29.5.3 Underside Appearance

When designing a structure, it is important to consider all visual vantage points: pedestrians, passengers in a boat passing beneath the structure, and passengers in vehicles driving underneath or beside the bridge. All have unique views of the bridge and can appreciate different aesthetic features. One example of specific aesthetic treatments that were used to enhance the visual appeal of the underside of a bridge is for the piers of the Broadway Bridge (Figure 29.26), which crosses the Intracoastal Waterway in the heart of downtown Daytona Beach, Florida. The bridge is viewed by boaters and pedestrians in the park along the water, so particular attention was paid to the vantage point from these perspectives. Building on the “Timeless Ecology” theme selected by the community, the elliptical piers are wrapped with a 10-ft-tall glass mosaic tile mural of manatees and dolphins. The mural is rotated by 10° on each subsequent pier, imparting a sense of movement to those who view the piers. Properly executed aesthetic lighting enhances the pier shape and lights the murals in the evenings.

FIGURE 29.26 Mosaic tile patterns on the piers provide visual interest for boaters under Florida's Broadway Bridge.

29.5.4 Creating Shadows

Shadows created by light interacting with the bridge features will vary with changing lighting conditions. Unique effects will be experienced as the light source moves and the shadows it casts change; therefore, features exposed to natural light will appear different at various times of the day as the sun moves across the bridge site. When evaluating shadowing effects due to the contour and shape of the bridge components, artificial nighttime lighting should also be evaluated, including both aesthetic lighting and roadway safety lighting. Elements should not be considered independently, as the overall bridge shape and individual superstructure and substructure shapes interact with each other to create ever-changing shadows. The prominent component of shadowing for a bridge is the superstructure. Minimizing shadows for elevated roadways may be accomplished with tall, slim piers to create a more open space for travelers underneath and beside it. The view from underneath may be enhanced with longitudinal lines or patterns cast into the superstructure that will produce an appealing shadowing effect. Changes in the superstructure cross-section through changes in the slope of the vertical web walls will also affect how shadows

FIGURE 29.27 Octagonal-shaped piers with concave surfaces help the piers of the Blue Ridge Parkway Viaduct blend with the mountain.

create the illusion of depth. Piers provide a great canvas for the creation of shadows. The use of vertical lines on piers through recesses or curved or chamfered edges will make the pier appear slimmer and more graceful or help the pier blend in with its environment. The pier cross-section of the Blue Ridge Parkway Viaduct (Figure 29.27) around Grandfather Mountain has an octagonal shape, which was enhanced with concave faces to create an effect of shadows, regardless of the direction of the sun.

29.6 Concrete Aesthetic Features

When the primary structural form has been determined for a bridge, specific details can be considered to further enhance the aesthetics and develop the overall theme. The use of color, texture, native materials, and other details of the aesthetic design can add greatly to the beauty of the structure, make it unique to its community, and provide continuity between bridge elements. In some cases, it is these details that define the structure.

FIGURE 29.28 Consistent concrete color was achieved on New York's AirTrain JFK, despite three mixing locations.

29.6.1 Introduction to Color and Texture

Advancements have been made in the aesthetic surface treatment of concrete in the last 10 to 15 years. Today, enhancing the appearance of concrete with color and texture is more economical and feasible from a constructability perspective than ever before. With foresight, strong specifications, and attention to construction operations, the color and texture of concrete can be lasting, low-maintenance features that contribute to the aesthetics of a bridge. Color and texture can be achieved in several different ways. The size and scale of the bridge or project area receiving color and texture may dictate which method or product is best suited for that application based on location, access, intricacy of the details, colors selected, availability of materials, and level of maintenance. It is important to note that when color and texture are added to the design careful consideration should be made as to how they will complement the overall shape of the bridge and bridge elements, lighting, shadowing effects, and patterns.

29.6.2 Overall Bridge Color and Texture

A seamless and unified look may be achieved through application of a uniform color or colorization of an entire bridge. How color is applied is based largely on the desired color, cost of labor and materials, and access. Each method has advantages and disadvantages, and each should be explored in light of the owner's project goals. The natural gray color of concrete can be visually appealing. This color is most attractive if consistency is maintained throughout via the use of single-source suppliers for aggregates, sand, and cement. An example of where this was achieved is the elevated structures of the AirTrain JFK in and around JFK Airport in New York (Figure 29.28). Specifications were developed to achieve a uniform concrete color, despite three concrete mixing locations. The superstructure segments were precast off-site in Virginia, the substructure elements were cast in place using concrete mixed off-site, and the superstructure closure joints were cast in place using concrete mixed by hand on the bridge deck. All of these elements have the same uniform color because specified materials and sources were used. If a lighter shade of gray or white is desired, white cement may be used. The use of single-source materials and white cement can potentially increase costs; however, it is a lifelong, maintenance-free method to achieve consistency in color and enhance the visual appeal of the structure.

FIGURE 29.29 Patterns and colors important to the local Native American culture were used on the pedestrian walkway of North Dakota's Four Bears Bridge.

Bridge coatings have been used extensively in the United States and can be manufactured in a wide variety of custom colors. They are favored by some bridge owners not only for the aesthetic value in achieving a uniform color and texture but also for their potential protective properties, as the coating serves as a sealant in addition to providing a uniform color. The colored coating is applied when the structure is nearly complete, much like paint.

Using colors similar to the surroundings of a bridge will help it blend in with the natural landscape. A natural color and slight roughened texture were achieved by using black iron oxide in the concrete mix which created a marbled appearance and helped the Blue Ridge Parkway Viaduct blend in with the rocky terrain of Grandfather Mountain in North Carolina (see Figure 29.27). Color achieved through the application of a coating can also be used to convey the theme of a project or help link the structure visually with local architecture. The Wabasha Freedom Bridge located in downtown St. Paul, Minnesota, was coated to blend with the cliff sides of the Mississippi River, adjacent to the bridge (see Figure 29.10). Another example of the use of color is the pedestrian walkway of the Four Bears Bridge in North Dakota (Figure 29.29). This primary transportation link to the Fort Berthold Indian Reservation has a wide pedestrian walkway that showcases images important to each of the tribes in the Three Affiliated Tribes who live on the reservation. Color patterns unique to each of the tribes are used in separate sections of the walkway surface, and a unifying pattern was added between these unique sections.

Where vertical recesses are cast into the pier, the use of color, especially a contrasting color, can highlight this area. The Lee Roy Selmon Crosstown Expressway Expansion in Tampa, Florida (Figure 29.30), has a smooth sculptured superstructure complemented by slim, tapering piers that have a vertical recess that follows the curved shape of the pier. Contrasting colors, achieved with a bridge coat, were selected for the pier inset and for the exterior of the pier and superstructure. The project consists of two separate structures: one in the more urban downtown Tampa area, surrounded by existing commercial properties, and the suburban end of the project, which traverses water features and vegetation. For the urban area, a light blue hue was selected for the exterior of the pier and superstructure and a contrasting off-white color for the pier recess. In the suburban section, a bolder, metallic blue was selected for the pier recess and the same off-white color was applied to the exterior of the pier and superstructure. The bolder, metallic hue of blue was customized by the manufacturer to achieve a mirrored or glassy look. Natural sunlight enhances this effect from different angles at various times of the day.

FIGURE 29.30 Contrasting blue inserts in the center of the piers for the suburban section of the Lee Roy Selmon Crosstown Expressway Expansion are appropriate in this Tampa neighborhood.

Another method to consider in achieving overall color is concrete stain. If a soft tone is desired and an irregular but overall color is ideal, then this is a viable method. Color achieved with this method penetrates the concrete to a depth of approximately 1/8 to 1/4 in. The stain does not conceal surface imperfections in the concrete; instead, it provides an overall tint to the surface. An example is the Interstate 70 Hanging Lake Viaduct (Figure 29.31), west of Denver, Colorado, where a light brown stain was used to blend the structure with the canyon walls.

29.6.3 Opportunities for Aesthetic Treatments

When the structural form and overall bridge color and texture have been defined, opportunities for localized aesthetic color and texture treatments can be explored. Some common areas for these types of local applications include piers, pylons, and pedestrian walkways. These surfaces provide a canvas for artistic expression and further development of the aesthetic theme of the bridge project. The Penobscot Narrows Bridge and Observatory (Figure 29.32) has a theme of “Granite—Simple & Elegant,” which is reflected in its obelisk-shaped pylons. Aesthetic details of the pylons include a 4-in. horizontal recess or articulation at alternating 5- and 10-ft spacing. The pylons were cast in place with 15-ft lifts; thus, the concrete was formed with articulations at construction lift lines that replicate the size of large blocks. These recesses were also used to hide the construction joints, and they blend well with the actual granite placed at the pylon base and observatory entrance, where the bridge is experienced on a human scale. The corners of the obelisk are chamfered to create simple, clean lines. Below the deck, the chamfer is 12 in. and above the deck, the chamfer is 8 in., thus maintaining the scale of the pylon dimensions.

29.6.4 Use of Native Materials

The use of native materials can be explored as an opportunity to blend a structure with its natural environment, convey an environmental or earthen theme, or develop community pride. An example of this is the Smart Road Bridge in Blacksburg, Virginia (Figure 29.33), which contains Hokie Stone in the pier recesses. Hokie Stone is acquired from a quarry owned by nearby Virginia Tech and is a stone that

FIGURE 29.31 A stain was used to blend the Hanging Lake Viaduct into Glenwood Canyon, Colorado.

FIGURE 29.32 The pylons of Maine's Penobscot Narrows Bridge and Observatory are obelisk shaped and include articulations that replicate large blocks of granite.

FIGURE 29.33 The pier recesses of the Smart Road Bridge are faced with Hokie Stone.

is prominently used throughout the Virginia Tech campus. Use of the stone on the bridge provides a visual link among the Virginia Tech Transportation Institute, the operators of Smart Road, and the Virginia Tech campus, while adding visual interest by utilizing materials in the bridge that are consistent with the mountainous environment.

29.7 Design Details

Bridge barrier rails, aesthetic lighting, landscaping, and other artistic details can increase the visual appeal of a bridge. Additionally, functional project components such as the location of drainage appurtenances and utilities should be considered for their visual impact.

29.7.1 Concrete Barriers/New Vistas

Crash-tested traffic barriers are required on bridges, and 32-ft-tall standard concrete barriers are typically installed. Bridges frequently offer unique vantage points for the driver, opening new vistas when a new crossing is higher than any existing site or offers a unique view. In situations such as these, where drivers might appreciate a better view from the bridge, open railings that meet the required safety standards as well as the typical solid concrete barrier have been utilized. As an example, the open railing on the Blue Ridge Parkway Viaduct provides uninterrupted views of the surroundings.

29.7.2 Drainage

When bridge deck drainage must be captured and not allowed to freefall onto the ground below, the water is collected at deck level and piped to an appropriate discharge location. These piping systems, although functional, often significantly detract from the appearance of a bridge; however, some inherent aesthetic benefits may be derived from a closed box girder with regard to drainage. Stormwater runoff may be collected on the bridge deck with curb inlets. Drainage piping from these inlets can be cast into the wings of the box girder, concealing the piping within the concrete, to convey the water to an internal stormwater piping system. This piping system can be designed integral to the pier and linked to an underground drainage system, at-grade swale, or other stormwater treatment facility. Unsightly drainage piping attached to the outside of the bridge structure can then be completely avoided. Pretreatment of the stormwater by oil/water separators in the inlets and outfall into a natural filtration system, such as a grassed swale, should be given great consideration not only to meet local, state, and federal requirements but also to develop a project that is environmentally sensitive. The Lee Roy Selmon Crosstown Expressway Expansion in Tampa, Florida, incorporated this type of a closed drainage system, eliminating unsightly exterior pipes while efficiently draining the roadway.

29.7.3 Utilities

Utilities are often carried along bridges. A closed box girder offers advantages by allowing the utility conduits to be carried within the internal core, hidden from view. Another benefit is that the utilities are protected from the elements and easily accessible if repair or modifications are required. The primary utility for any bridge project is electricity, which may be required for roadway lighting, interior box lighting, or exterior aesthetic lighting. Electric conduits can be placed inside the box, either cast into the concrete itself or attached to the underside of the top slab with utility hangers. Other utilities may also be installed inside the box girders. This can be an advantageous approach to crossing a body of water for a utility company vs. installing utility poles to cross overhead or tunneling underneath the body of water. When incorporating utilities into the bridge design, loading and attachment to the inside of the box must be considered, in addition to the pipe material, curvature of the pipe as it follows the geometry of the bridge, potential high voltage (heat), and installation of fiber telecommunication lines. When determining the feasibility of carrying a utility inside a bridge, the bridge engineer must determine what might happen if the utility fails, such as the rupture of a high-pressure water line. In this case, the bridge engineer must address how this water can be removed quickly and safely. The following should be required if utilities are installed within the box girder: regular inspection of the utility pipelines and appurtenances, installation of devices that will alert the appropriate utility company of leaks or other failures, and establishment of emergency response plans. Installing utilities inside a bridge requires a great deal of communication with the utility companies and their engineers, and the design of the bridge must accommodate these utilities. Concealing these utilities rather than attaching them to the outside of the structure or having them cross overhead adjacent to the structure will greatly enhance the visual aesthetics.

29.7.4 Aesthetic Lighting

Lighting can set a bridge apart from other structures in a city's skyline by creating a unique nighttime signature. Lighting can greatly enhance the beauty of a bridge and improve vehicular safety. A good example of aesthetic lighting is the Chesapeake and Delaware Canal Bridge near St. Georges, Delaware (Figure 29.34). Subtle lighting on the pylons and cable stays illuminates the bridge shapes, making the pylons quite distinct at night. Blue uplighting on the angularly shaped pylons of the Leonard P. Zakim Bunker Hill Bridge in Boston, Massachusetts, enhances the beauty of this structure and highlights the various planes of the cable stays at night. Property values near the bridge have increased since construction was completed, and the skyline is enhanced by this signature bridge. Decorative roadway lighting fixtures can also be used to enhance the experience of pedestrians and passengers using a bridge; for example, poles on the Broadway Bridge in Daytona Beach, Florida, display banners promoting city events.

FIGURE 29.34 The Chesapeake and Delaware Canal Bridge has aesthetic lighting suitable to its less populated location.

29.7.5 Landscaping

When a bridge is designed with minimal disturbance to its surroundings, the natural landscape is preserved. When a structure is constructed in an area without landscaping, adding green spaces can greatly enhance the areas surrounding the bridge. Landscaping and a gazebo fill the spaces beneath the 17th Street Bridge in Ft. Lauderdale, Florida. These new spaces invite the public to the riverfront and provide a connection among the surrounding venues. Consideration of the landscape and creating greater green space is important to sustainable design.

29.7.6 Innovative Technologies

New technologies have arisen out of the desire for economy, aesthetics, and efficiency. An example is the Veterans' Glass City Skyway Bridge in Toledo, Ohio, where the community wanted to showcase their glass industry heritage. This state-of-the-art, cable-stayed bridge has a single, slender pylon, the top portion of which features four sides of glass. To achieve the desired slender pylon shape and to simplify the construction and maintenance of the cable-stay system, a new cradle system was developed that allows the cable stays to pass continuously through the top of the pylon, eliminating the need for anchorages (Figure 29.35). This system reduced the size of the pylon, resulting in lower costs and an ability to accommodate the glass aesthetic feature. The cradle system also facilitates inspection and maintenance by permitting removal and replacement of the strands to monitor their condition throughout the life of the bridge. This new development resulted in a low-maintenance, efficient solution while addressing the community's aesthetic desires.

29.7.7 Artistic Details

The artistic expressions in a bridge can celebrate its sense of place. Broadway Bridge in Daytona Beach, Florida (Figure 29.36), conveys the theme of "Timeless Ecology" throughout the project, but perhaps the most enjoyed element of the design is a permanent art gallery on display along the bridge sidewalks.

FIGURE 29.35 The new cradle system simplifies design and long-term maintenance while allowing for greater flexibility in pylon shape (shown is a cradle pipe that runs through the pylon).

FIGURE 29.36 Broadway Bridge in Daytona Beach provides pedestrians with an art gallery of glass tile mosaics along the walkways.

Both sidewalks showcase 18 precast concrete panels containing glass mosaic tile murals of various species indigenous to the Atlantic coast. The murals may be seen by pedestrians and motorists using the bridge. The back of the panels, as seen from the water, contain identical cast relief shells on a sea blue background of glass mosaic tile. The connection of finer details can create the uniformity of artistic expression of the form of the bridge and the message the bridge conveys.

29.8 Summary

Bridges are both structure and symbol. Their functionality serves the public good by connecting people and places to enhance the quality of life. As important infrastructures on the landscape, they should merge sustainable design and aesthetic beauty. Proper alignment, geometry, span arrangements, superstructure, and substructure shapes and the application of aesthetic design principles must be considered from the viewpoint of both good design and efficient construction. The future of modern concrete bridges recognizes the inherent qualities of redundancy and the advanced knowledge that can be gained from “smart bridge” technology. Sensors and high-tech monitoring devices can smartly guide future opportunities to streamline the final designs of bridges. Advanced concrete materials with improved strengths,

FIGURE 29.37 A functional sculptural bridge (I-35W, St. Anthony Falls Bridge in Minnesota) reflects a series of modern arch forms softly set in the context of the site to maximize openness, light, green space, and a focus on the river.

FIGURE 29.38 The pier shape creates a reflection of curved forms with continuous movement into the bridge superstructure (I-35W, St. Anthony Falls Bridge in Minnesota). Two main piers feature observation platforms along the edge of the river. The appearance underneath creates a visually clean and quiet space.

density, and placement flexibility are being used today to the benefit of functional, yet sculptural bridges. The St. Anthony Falls Bridge (I-35W) in Minneapolis, Minnesota, utilizes long, variable-depth, concrete box girder prestressed spans (504 ft over the Mississippi River), as well as sculptural curved pier shapes (70 ft tall), an open greenscape, lighting, and aesthetic features that highlight a modern concrete bridge focused on simple elegance (Figure 29.37 and Figure 29.38). Future bridges will blend shapes and maximize the repetition of form for redundancy of strength and efficiency of construction. Designers of concrete bridges should remain ever mindful of their responsibility to current and future generations to create bridges that celebrate the technology of the time and the community's sense of place.

“Reflections”—precast, high-strength polymer concrete artwork by the Civil Engineering Class of 1982 with Profs. R.H. Karol and E.G. Nawy, Rutgers University. Each slice was cast separately; the slices were assembled and epoxied together to form the thinking lady statue. (Photograph courtesy of Edward G. Nawy.)

30.1 History of Architectural Cast-in-Place Concrete

30.1.1 The Beginning (Prior to 1965)

Le Corbusier's Carpenter Center at Harvard University is one of the first recognized uses of architectural concrete in the United States. This daring project, along with several others in Europe, triggered a marked interest and excitement among designers in the United States. As using concrete as an architectural medium became an identifiable trend, the architectural concrete industry evolved with the speed of a fad and left an enduring impression on the construction industry. If there was a specific turning point in the acceptance and use of architectural concrete in the United States, it seems to have come with I.M. Pei's Kips Bay apartment complex in New York City, although a number of other projects were in the planning and building stages at about the same time. Outstanding achievements can be attributed to I.M. Pei; Eero Saarinen; Minoru Yamasaki; Sert, Jackson, and Gourley; Paul Rudolph; Skidmore, Owings, and Merrill (SOM); Pier Luigi Nervi; Phillip Johnson; The Architects Collaborative (TAC); and many others. Of special importance is the fact that the designs created by the architects listed have no common approach. Each is distinctive. Most of our finest examples of architectural concrete take advantage of the free-form plasticity of the material but show complete recognition of the intense discipline it requires. Where this discipline and attention to detail have not been given proper consideration in other projects, the results have been disappointing. Unfortunately, the designers frequently attribute this deficiency to the contractor's lack of knowledge. Although this may be part of the problem, it cannot account for some of the early failures.

30.1.2 Prime Years (1965–1990)

From 1965 to 1990, the use of architectural concrete bloomed. Sculpturing of the forms, better quality form liners, innovative concrete mix designs, and improved placement and consolidation procedures dramatically improved color uniformity and texture. During this period, architects such as I.M. Pei and Partners; SOM; Hellmuth, Obata, and Kassabaum (HOK); Roy P. Harrover; Greiner Engineering; Sikes, Jennings, and Kelly (Figure 30.1); Newhouse and Taylor; Rex Whittiker and Allen; Welton Becket; and others led the way.

30.1.3 Current and Future

Architectural design has gone through cycles, but architectural concrete began making a comeback in the late 1990s, when Polshek and Partners completed the Inventors Hall of Fame in Akron, Ohio, using architectural cast-in-place concrete. I.M. Pei and Partners completed the Rock and Roll Hall of Fame in Cleveland, Ohio; the National Airlines Terminal at JFK International Airport in New York; and the U.S. Holocaust Memorial Museum in Washington, D.C. Tadao Ando and Santiago Calatrava are the new stars of architectural concrete design. Ando's Pulitzer Art Museum in St. Louis and his Museum of Modern Art in Fort Worth (Figure 30.2) reflect the ruggedness and versatility that are inherent in architectural concrete. Calatrava's almost miraculous displays of concrete demonstrate a grace seldom seen in earlier concrete projects. Projects in Mexico, Europe, and Southeast Asia, where concrete is a widely available material, have eclipsed those in the United States. In spite of the many successes in both commercial and monumental types of construction, architectural concrete has experienced periods of very flat or declining growth, perhaps due to marginal aesthetic results caused by a lack of understanding by designers and contractors regarding the architectural concrete process. High labor costs, difficulties in obtaining a reliable finished product, and possible delays in project completion all work against selection of architectural cast-in-place concrete. Early construction planning can reduce all of these negative factors. Contractors have stated that every dollar spent in planning has saved \$4 to \$6 in construction costs. Early planning or a prebid conference that includes the approved contractors, ready-mix suppliers, architect, and owner is essential to familiarize everyone with the drawing details, specifications, sample mock-ups, and quality of concrete work anticipated for the project. Proper budget estimates must be prepared. Architects and contractors must be willing to produce the structure with a minimum amount of mistakes

FIGURE 30.1 First United Tower, Fort Worth, Texas; architect, Sikes, Jennings & Kelly, Houston; medium, sandblast texture.

and surface blemishes. No matter how good the conceptual design, a building can be ruined by dark lines, pour lines, blotchiness, discoloration, or variations in texture. Architects in recent years have taken a cautious approach to the use of architectural cast-in-place concrete due to the potential pitfalls that can result in owner dissatisfaction.

30.2 History of Architectural Precast Concrete

30.2.1 The Beginning

The first documented modern use of architectural precast concrete was by Auguste Perret in 1923 for the Cathedral Notre Dame Du Haut in Raincy, France, although it was used only as screen walls and infill in an otherwise cast-in-place concrete structure. The depression years followed soon after and then the cataclysm of World War II. Not until World War II ended did the architectural use of precast concrete begin to flourish. Surface finishing techniques for architectural precast concrete, such as water washing and brushing, bushhammering, sandblasting, and acid etching, were initially developed for cast-in-place concrete, as was obtaining colored surfaces by means of pigments and special colored aggregates. These techniques were also well established within the cast stone industry by the 1930s.

In 1932, John J. Earley and his associates at Earley Studio in Rosslyn, Virginia, began work on producing exposed-aggregate ornamental elements for the Baha'i Temple in Wilmette, Illinois (1920–1953), one of the most beautiful and delicately detailed architectural precast concrete projects in the United States. The panels are white concrete with exposed quartz aggregate. Lack of funds postponed completion of the exterior precast concrete until 11 years after the building was begun. Another early notable use of large precast panels was for the White Horse Barn (1937), constructed for the Minnesota State Fair. This structure had panels 15 ft long, 7 ft high, and 6 in. thick. Cast with a smooth finish and cured for 7 days in steam-filled rooms, these panels were attached by the structural concrete around the edges of the panels.

A pivotal development occurred in 1938, when administration buildings at the David W. Taylor Model Testing Basin were built near Washington, D.C. Panels 2-1/2 in. thick and up to 10 ft by 8 ft were used as permanent forms for cast-in-place walls. The project was significant as the first use of the Mo-Sai manufacturing technique, with units produced by John Earley in collaboration with the Dextone Company of New Haven, Connecticut. It was also the first project in which large-area exposed-aggregate panels were adapted to serve as both the exterior form and preinspected facing for reinforced concrete building construction. Earley had patented the idea of using step (gap)-graded aggregate to achieve uniformity and color control for exposed-aggregate work. Working from this background, the Dextone Company refined and obtained patents and copyrights in 1940 for the methods under which Mo-Sai Associates (later Mo-Sai Institute, Inc.) operated. The Mo-Sai Institute grew to include a number of licensed manufacturing firms in various parts of the United States. Its public relations and advertising activities, highlighting technical achievements, were a major factor underlying general acceptance of architectural precast concrete. The surface finishes produced by the Mo-Sai process were dense, closely packed mineral aggregate with a minimum of cement/fines matrices that resembled mosaic, from which the name Mo-Sai was derived.

In 1958, a new panel-casting method was introduced in the United States under the name of Schok-beton (shocked concrete), and a number of franchised plants were established. The machinery used in this method was patented in Holland in 1932. The process is primarily a means of consolidating a no-slump concrete mixture by raising and dropping the form about 5/16 in. some 250 times per minute. This contrasts with conventional methods of consolidation using high-frequency and low-amplitude vibration. Although the production of large precast panels by this method was relatively new, small concrete units had been produced in the past on so-called drop tables, which followed the same technique without the refinement of modern machinery. Depending on the cement content, the shocking technique produces compressive strengths of 3000 to 4000 psi after 24 hours and up to 10,000 psi at 28 days.

Architectural precast concrete usage initially was complicated by the lack of mobile cranes and other efficient material-handling equipment. Because of this lack of equipment and because of competition from metal and glass curtain-walling, precast concrete was comparatively slow to develop, and the record of its eventual rise to parity, even its dominance in places, is properly that of the 1960s. Reasons for this expanding usage were improved methods of production, better handling and erecting equipment, and the realization that precast panels provided a pleasing variety of surface textures, patterns, and exterior designs that generally could not be accomplished as economically in other materials. A number of

pioneering early postwar uses of precast concrete in architecture were otherwise of limited significance. These included dormitory units at the University of Connecticut (1948) based on load-bearing wall panels; an eight-story office building in Columbia, South Carolina (1949), with window-wall cladding panels (erected by hand winch); and a six-story office building in Miami (1951) where 4-in.-thick precast panels were suspended from the soffit of a cantilevered cast-in-place floor slab.

The Hilton Hotel in Denver was completed in 1958/59 and was one of the early significant uses of window-wall panels fixed to a structural frame. The Police Administration Building in Philadelphia, completed in 1962, made history as one of the first major buildings to utilize the inherent structural characteristics of architectural precast concrete. Its exterior panels, 5 ft wide by 35 ft high (three stories), carry two upper floors and a roof. This structure was an early model for the blending of multiple systems (precasting and post-tensioning) for one building.

30.2.2 Current Practice

Architectural precast concrete can be provided in almost any color, form, or texture, making it an eminently practical and aesthetically pleasing building material. It is difficult to imagine an architectural style that cannot be expressed with precast concrete. By providing the designer complete control of the ultimate form of the facade, the precast concrete industry has experienced steady growth since the explosive 1960s, particularly in the ever-widening range of precast concrete applications. The widespread availability of architectural precast concrete, the nearly universal geographic distribution of the necessary raw materials, and the high construction efficiency of prefabricated components all add to the appeal of architectural precast concrete construction. Established precasters have a high level of craftsmanship and ingenuity along with a thorough knowledge of the material and its potential for converting the designer's vision into a finished structure.

30.3 Applications

30.3.1 Cast-in-Place

Architectural cast-in-place concrete has been used in many colleges; libraries; airport terminals; office buildings; museums; public buildings for city, state, and federal government; hospitals; sound-barrier walls; industrial warehouses; and all types of landscaping products.

30.3.2 Precast

The use of nonload-bearing precast concrete cladding has been the most common application of architectural precast concrete. Cladding panels are those precast elements that resist and transfer negligible load from other elements in the structure. Generally, they are normally used only to enclose space and are designed to resist wind, seismic forces generated from their self-weight, and forces required to transfer the weight of the panel to the support. Cladding units include wall panels, window-wall units, spandrels, mullions, and column covers. Their larger dimension may be vertical or horizontal.

Often the most economical application of precast concrete is as a loadbearing element, which resists and transfers loads applied from other elements. With very few modifications, many cladding panels may function as loadbearing members. The steel reinforcement required to physically handle and erect a unit is often more than that necessary for in-place loads. The slight increase in the load-bearing wall-panel costs (due to erection and connection requirements) can be offset by the elimination of separate structural framing (beams and columns) from exterior walls or the reduction of interior shearwalls. This savings is most apparent in buildings with a large ratio of wall to floor area.

In many structures, it is economical to take advantage of the inherent strength and rigidity of exterior precast concrete wall panels and design them to serve as the lateral-load-resisting system (shearwalls) when combined with the diaphragm action of the floor construction. A current trend is toward the use of precast concrete units as forms for cast-in-place concrete. This system is especially suitable for

combining architectural (surface aesthetics) and structural functions in load-bearing facades or for improving ductility in locations of high seismic risk. Because the cost of formwork is a significant part of the overall concrete cost in a structure, substantial savings can usually be achieved by using precast concrete units as formwork. In addition to functioning as exterior and interior wall units, precast concrete finds expression in a wide variety of aesthetic and functional uses, including: (1) art and sculpture; (2) lighting standards and fountains; (3) planters, curbs, and paving slabs; (4) balconies; (5) screen sound barriers and retaining walls; (6) screens, fences, and handrails; (7) street furniture; and (8) ornamental work.

30.3.3 Decorative Floors

Concrete floors have not traditionally fallen into the category of *architectural concrete*; however, since 1990, there has been a dramatic rise in the artistry and variety of decorative concrete floors. Concrete floors embossed with stamped patterns, pigmented with integral pigments, or treated with applied stains have become extremely popular. Polished concrete floors have become common in big-box retail stores, which have discovered that exposed concrete floors are a lower cost alternative to resilient flooring or carpet. Although decorative floors can be considered as architectural concrete, they require a different scope of expertise than formed concrete and are not addressed in this chapter.

30.4 Planning

30.4.1 Budget

Regardless of the type of building or its intended use, the architect and owner must begin with a budget estimate. Although forming, placement, concrete, and finishing costs will undoubtedly be more for an architectural concrete job, the end cost of the completed building might well be less than the total cost of a structural concrete job when rental income, maintenance costs, additional finishes, architectural treatments, and repair costs are factored into the equation. Life-cycle costs are what interest the owner. Architectural concrete projects must have an adequate budget to achieve the desired visual impact while maintaining the integrity of the structure. When the design architect has determined the image and scope of the project, an initial meeting should be held that includes the architect, architectural concrete consultant, structural engineer, and landscape architect, if one is associated with the project.

At this time, shape vs. structural requirements and precast vs. cast-in-place are evaluated. The capability of local precast facilities and availability of knowledgeable concrete contractors often determine the most economical approach to achieve the finish appearance required. The designer must decide at this time whether to follow the possibility of form and continuity inherent in cast-in-place concrete or the building-block logic, time savings, and precise quality control of precast. Relative costs can vary with time and place. Repetition is essential to maximize economy for precast concrete components. Careful planning is necessary to achieve good repetition without sacrificing design freedom.

The type of finish selected can have a large impact on budget. The architect must provide sufficient funds in the budget to allow the special finish and quality workmanship required for the method selected and must determine whether specialized construction techniques are routinely accepted and executed by local contractors. Casting structural concrete against a form liner or sandblasting the surface does not necessarily produce acceptable architectural concrete. A contractor that assumes this is about to learn an expensive, time-consuming lesson and will probably have an unhappy client who is not receptive to scheduling future projects with the firm. The secret to successful architectural concrete is early and detailed planning. Final costs and execution do not end with the building designer, but with the contractor. The general contractor must know how to carry out the designer's intentions without increasing the contractor's or owner's costs. The contractor must have knowledgeable workmen, especially for the forming and concrete superintendents. Current bidding practices often result in late award of the precast subcontract. In practice, this means that additional molds must be built to meet the project deadline. The necessity for extra molds increases costs and partially offsets the use of high repetition.

FIGURE 30.3 Waviness in the concrete surface due to lack of form rigidity during concrete consolidation.

The secret to good architectural concrete is in the forming. Forms must be strong enough to accomplish concrete placement within specified form joints and rustications without honeycomb, cold joints, or pour lines. A superintendent who has placed many thousands of yards of structural concrete where strength and a lack of honeycomb have been the criteria could be in trouble when visual excellence is required if strict attention is not paid to details.

30.4.2 Drawings

Eventually, the conceptual design must be detailed and working drawings completed. Construction elements such as control joints, construction joints, form-tie locations, concrete shrinkage, reinforcement location, reinforcement coverage, special form requirements, mix design, concrete access points, and type of finish must be considered. The contractor should pay special attention to closure technique or concealed joints in formwork. Articulated lines or rustications should be drawn at the control and construction joints. The closer the architectural concrete construction follows the natural construction sequence, the more economical the costs. In addition to the formwork items discussed below in Section 30.7.1, the contractor must consider form rigidity. Architectural concrete often includes high columns and walls. Forms must be sufficiently reinforced to eliminate wave action or pulsating action as well as form movement during the use of high-frequency vibrators (Figure 30.3). Form height is a function of drawing details involving rustication details and form-tie locations. Repetitive items in design will increase form usage and allow higher quality forms (such as steel or fiberglass) to be used economically.

The contractor needs to ensure that the drawing details work. Although the architectural concept of the drawings may be excellent, if the details do not work then the building has the potential to be a failure. Good design considers the construction needs as well as the architectural and structural criteria. The drawings set the conditions under which the contractor must work. A wall designed to be 8 in. thick, including a double curtain of reinforcing, will not allow proper concrete placement and consolidation because the space is simply too tight. If the wall has rustications and minimum cover requirements on the outside face, space requirements for vibrator placement get even tighter. Allowing for acceptable tolerances on the placement of reinforcing steel will place even tighter access for the vibrator.

Cast-in-place architectural concrete and precast elements may be successfully combined but require detailed effort on the part of the architect and an understanding of the construction process for each system on the part of the contractor. More time will be required for the selection of materials, mix

FIGURE 30.4 Matching architectural cast-in-place and precast concrete at King Saud University in Riyadh, Saudi Arabia; architects, HOK, St. Louis, MO.

designs, and finishes than if only one system were used. Realistically, large mock-ups and knowledgeable workmen must be part of the contractor's production process.

The architect has a great deal of freedom of expression in working with architectural concrete. An architect may select thin members or sculptured shapes in precast concrete and combine them with the massiveness and structural strength of cast-in-place concrete to create the curtain wall (Figure 30.4). Today, when costs for different types of facades are compared, precast or cast-in-place concrete can be competitive and compare very favorably with glass and metal facades. Design can provide either matching or contrasting colors between architectural precast and cast-in-place concrete.

The precaster's shop drawings (erection and production drawings) should be prepared in general conformance to the *PCI Drafting Handbook* (PCI, 1990). Generally shop (erection) drawings are submitted to the general contractor who, after checking them and making notations, submits them to the architect/engineer for checking and review. Timely review and approval of shop drawings and other pertinent information submitted by the precaster are essential, as fabrication should not commence until final approval or an approved-as-noted has been received.

The architect reviews the precaster's erection drawings primarily for conformance to the specifications, then passes them along to the structural engineer so he can check for conformance to the specified loads and connection locations. This allows the engineer to confirm his own understanding of the forces for the structure at the connection points and the precaster's understanding of the project requirements. Design details, connection locations, and specified loads should not be left to the discretion of the precaster. This is especially important in cladding panels, where the weight of the unit and its torsion and shear must be supported by the frame. Steel frames are more sensitive to the eccentricity of a panel unit causing deformation of the structure and may require bracing.

30.4.3 Specifications

Specifications can be a trap for the unwary contractor. Reference may be made to architectural concrete requirements in the general concrete specifications. When projects, including several monumental buildings, have had high budget estimates, the separate section for architectural cast-in-place concrete has sometimes been removed from the specification. All concrete has been covered under the general concrete section. A short added paragraph may read something like this: "The final finish surface should be a

uniform light sandblast and match the approved sample panel in Architect's office." A short paragraph near the end of the concrete section may state: "No patching or repairs will be permitted without the express permission of the Architect. Only patching of minor blemishes will be permitted." These short paragraphs added to a general concrete specification can be deadly to the contractor. No mention is made of special mix requirements, mock-ups, form or form-tie locations, placing consolidation, and finish requirements. Architectural cast-in-place concrete specifications should be used and clearly separated from those for general concrete, and the contractor should always prepare a mock-up for approval whether or not one is specifically called for in the specification. The mock-up can consist of a segment that will be incorporated in the finished structure.

Specifications can be both the friend and ally of the owner, architect, and contractor. Architectural concrete is not structural concrete with only a surface finish applied. It is a material that requires a special process leading to the final finish required. Both architectural cast-in-place and precast concrete must be clearly specified, closely supervised, and produced throughout the full construction process by knowledgeable workers who care. Architectural precast should always have a separate section in the contract specifications, as should architectural cast-in-place concrete.

The two basic types of specifications are *performance* and *prescriptive*. A pure performance specification is one that references a physical sample of concrete. It essentially says: "Produce concrete that looks like the referenced sample and meets all other concrete requirements as contained in the general concrete section." Such a specification assumes that this type of concrete finish is not new and has been satisfactorily produced before by all parties concerned. On the other hand, a prescriptive specification is necessary when the bidding list must be left open or when the finish is a new type developed by the designer. This type of specification relies on the detailed investigation of materials, mix designs, formwork, concrete placement procedures, and methods of finishing. It then gives explicit instructions on what procedures to follow. Even though instructions may be clear, a prescriptive specification requires constant supervision to keep everything rolling smoothly (Bell, 1996).

The performance type of specification is the most practical. It can be used when (1) a physical example of the concrete finish is available, (2) the contract is negotiated or only prequalified bidders are selected, or (3) craftsmen are available to produce the required performance (Bainbridge and Abberger, 1994). Too often a contractor is asked to comply not only with standards from the American Society for Testing and Materials (ASTM), American Concrete Institute (ACI), Precast/Prestressed Concrete Institute (PCI), and others, but also with references, guides, or practices published by the above because they are incorporated by reference in other documents mentioned in the contract even though no copies or details are furnished. To clarify this issue, in 1978 the American Concrete Institute published the following policy that is used today on all appropriate documents: "ACI Committee Reports, Guides, Standard Practices, and Commentaries are intended for designing, planning, executing, or inspecting construction and in preparing specifications. Reference to these documents shall not be made in the Project Documents. If items found in these documents are desired to be part of the project documents, they should be incorporated directly into the project documents."

30.4.4 Quality Control and Quality Assurance

In theory, for commercial-grade concrete construction, the contractor simply hires a testing laboratory approved by the owner or architect and sees that the reports are distributed to the responsible parties. The contractor should review ready-mix concrete facilities and local precast manufacturers for service history; reserve capacity; availability of modern trucks; plant silo, bin, and storage capacity; and availability of knowledgeable and cooperative personnel. Owners are looking for contractors to spend more time and money in construction reviews and in planning to develop more innovative ways to meet schedules and improve quality. More monumental work is being negotiated or has a very limited bid list. Contractors with prior experience in architectural concrete who can meet budget performance, maintain good safety records, and control the project processes will be in high demand (Bainbridge and Abberger, 1994).

The basic purpose of quality-control programs is to ensure that the requirements of the contract documents are met in every step of the process, from selection of materials to curing of the concrete. Written records are required to substantiate that fact. Top management personnel in construction companies need to educate their talented field people with regard to the benefits of quality control (QC) and quality assurance (QA). The contractor works for the owner and is responsible for constructing the project as designed and specified. He must ensure that the quality of construction measures up to or exceeds the standards of material and workmanship required by the contract documents. This is the contractor's primary responsibility, but the contractor must also emphasize to employees, material suppliers, and subcontractors the importance of searching for errors in design or specification and selection of inappropriate materials. Although design review is not part of the contractor's responsibility, it may be good insurance to seek a second opinion on soils engineering, structural engineering, exterior-facade details, etc. Replacing or redoing problem construction is time consuming, frustrating, and always expensive.

The contractor cannot cite lack of skilled workers, irresponsible subcontractors, or rushed or incomplete drawings as an excuse for poor quality. In today's construction environment, the contractor must live with tight budgets, low construction time, drawings that are completed as construction progresses, and lack of skilled workers. What better reason could there be to cry for improved quality control and quality assurance programs? Quality control is directed toward after-the-fact inspection and testing. Quality assurance is a broader concept that involves planning and a program that incorporates feedback from site problems, inspection, and testing. Quality assurance programs incorporate both feed-forward and feedback controls for each segment of the construction process. Quality assurance is when the contractor:

- Makes sure the field supervisors and subcontractors recognize the obligations of the contract documents
- Thinks *quality* in every decision made
- Identifies project risks and relates them to quality factors as well as time and costs
- Coordinates and communicates with the architect/engineer and owner with overall quality in mind
- Encourages all of the workers to concern themselves with the quality of construction
- Uses knowledgeable consultants to assist in planning and on-site review
- Anticipates problems and tries to alleviate them early
- Learns to listen
- Minimizes reworking or rebuilding

The most profitable projects are those that prevent defects in the first place through planning, communication, and ongoing QA programs.

An architectural precast concrete manufacturing plant should be certified by the PCI Plant Certification Program at the time of bidding. Certification should be in product group A1 (architectural concrete). The certification of a producing plant by PCI indicates that the plant has in place a system of quality, starting with management. Further, the quality system extends to all areas of plant operations including a thorough and well-documented quality control program. Certification indicates that plant practices are in conformance with time-tested industry standards. It means that the plant regularly demonstrates its ability to produce quality products. All plants are audited at least twice each year. Audits are unannounced and are usually of 2 days' duration. Audits and grading are based on the *PCI Manual for Quality Control for Plants and Production of Architectural Precast Concrete Products* (PCI, 1996). The audit covers all aspects of production and quality control as well as engineering and general plant practices. The product evaluations performed by in-house quality control personnel are also reviewed to determine if routine monitoring is correct and accurate.

30.4.5 Prebid Conference

A prebid conference should be held at least 3 weeks prior to bid. This conference should involve all of the professionals in the design team, preselected general contractors, and anticipated precast manufacturers. In addition it may include interested formwork, reinforcing steel, and concrete producer subcontractors.

Precast manufacturers should have submitted their samples, company brochures, technical literature, and proposed materials prior to the meeting. Plans for how the work is to be accomplished in accordance with the requirements of the contract documents would be available at this meeting. The architect should have the building model and any samples showing anticipated color and texture. On exceptionally large projects, an extra mock-up may be constructed, under a special contract, to be available at the prebid conference. This mock-up would help determine the feasibility of various materials, treatments, and construction procedures prior to writing the particular architectural specifications for bid. Contractors would be told what is expected in the way of workmanship, timing, and results. Samples would be discussed and material sources and adequacy of reserves reviewed. Precast production schedules, plant facilities, and personnel would also be discussed. At this meeting, potential problems would be addressed and the final architectural finishes clearly spelled out. Generally, one prebid conference is held for all anticipated contractors, subcontractors, and precast manufacturers.

30.4.6 Preconstruction Conference

Following award of the contract, the architect should schedule a preconstruction conference with the contractor at a time and place that are mutually agreeable to discuss the architectural concrete system. This allows the design team to meet with the contractor, the contractor's key personnel, the ready-mix concrete supplier, the form supplier, reinforcing and placement subcontractors, the testing laboratory, and the precast supplier (if applicable). Brochures or literature should accompany any alternative construction proposals. Patented form systems may be suggested at this conference. The contractor should be sure such systems not only meet structural needs but are also appropriate for architectural purposes. Butt joints or form-tie locations may be a problem with certain form systems. When precast and cast-in-place construction are to match, the precast manufacturer should match the cast-in-place construction. The precaster has more flexibility in matching color and texture than the cast-in-place contractor, who does not have as many options and specialty techniques available. The preconstruction conference is a good place to set ground rules and begin planning quality assurance programs. At this meeting, the design team should be responsive to suggestions and requests for approvals and additional information by the contractor. The architect should be responsive to alternative plans submitted by the contractor and make recommendations for the contractor's consideration. The contractor must be ready with a plan of construction, timing, and schedule of items that involve the design team such as mock-up timing, shop-drawing approvals, and any remaining questions as to color or texture.

30.4.7 Mock-Up Construction

Mock-up construction is where the contractor demonstrates the intended results. Materials, equipment, and construction methods used are those intended for the actual work. The mock-up should be a full-scale mock-up and contain a full complement of reinforcing steel and blockouts. The mock-up is a proving ground to test the design details, shape, construction-joint locations, gasket procedures, and finishes required under the contract documents. In the case of alternative proposals, the mock-up helps ensure that the intent of the designer is understood. For the contractor's own protection, every architectural concrete project should include a mock-up or mock-ups. This is true whether or not one is specified.

A cast-in-place concrete project may have only one large mock-up showing a column, beam, or wall section that is full scale in size and uses the design reinforcing, forming system, concrete mix, placement procedures, and consolidation methods to be used in the actual work. After completion and approval of the construction, the mock-up is used to demonstrate cleaning, repair techniques, sealers (if specified), and protection. An architectural precast project might require three mock-up samples of a size sufficient to demonstrate actual planned production conditions. Any mock-up or combination of mock-ups must be able to establish the range of acceptability with respect to color and texture variations, surface blemishes, uniformity of corners or returns, frequency and size of air-void distribution, and overall appearance. Mock-ups also test the planning and training abilities of the contractor. Mock-up usage should shorten the learning process and set the standards necessary to achieve the designer's objective.

The mock-up should be prepared or erected at the job site and be approved before the majority of the formwork for the architectural concrete construction is built or purchased. When forms are to be site made, the mock-up must be finished at least 45 days before the architectural concrete is scheduled to be cast. On larger cast-in-place projects where custom-built forms are to be used, the mock-up should be finished 90 to 120 days before forms are needed for construction. This will allow time to revise the forms or the construction methods used in the construction of the mock-up. This long lead time can be necessary. Do not let the project be delayed by inadequate planning and lead times. Construct as many full-size mock-ups as necessary to meet the approval of the architect. When a mock-up is not called for in the specifications and the concrete called for appears to be structural concrete with only a light texture finish, a contractor would be wise to go through a sample and mock-up procedure at his own expense prior to final decisions on mix design and formwork purchase. The samples and mock-up for cast-in-place concrete may have to be scaled down due to the cost factor but should not be eliminated from the early phase of the construction process. Sometimes future architectural cast-in-place concrete may use part of the early structural concrete as a testing ground for forming and concrete placement. Areas hidden from view such as basement walls or elevator shafts could be used. Some type of mock-up construction will minimize any confusion on the part of all parties involved in the project design and construction.

Approval of any mock-up should be based on the full mock-up or, in the case of precast, of at least three precast full-scale (not necessarily full size) samples. Realistically, all architectural concrete surfaces will have blemishes, irregular surfaces, and differences in color and texture. Samples and mock-ups should be used to establish the range of acceptability prior to the beginning of actual construction. Mock-ups should remain on the job site or at the plant where they are readily available for inspection and comparisons until completion of the work (Figure 30.5). Mock-ups can be most effectively assessed when presented in their final orientation: horizontal, vertical, or sloping. Details should be viewed from a distance typical for viewing the architectural concrete on the building but that is not less than 20 ft. Reference to another project or an adjacent building should never be the basis of the architectural color and texture demanded for a project. Mock-ups should be required for each project. A different building facade may have been produced under special conditions involving different specifications, use of materials no longer available, or more stringent supervision requirements.

30.5 Materials–Mixture Design

Certain variations, mix proportions, and procedures are specific to architectural concrete. A change in aggregate proportions, color, or gradation will affect the uniformity of the finish, particularly where the aggregate is exposed. In smooth concrete, the color of the cement (plus pigment) is dominant. A matte finish will result in a different color than a smooth finish. If the concrete surface is progressively removed by sandblasting, acid, tooling, retarders, or other means, the color becomes increasingly dependent on the fine and coarse aggregate. Darker and more colorful fine aggregates have more influence when used with lighter colored cements and especially with white cement. When there is a significant difference in contrast between the paste color and the aggregate color, variations in finishing will be more apparent. When the paste color is similar to the aggregate color, variations in finishing will be less apparent.

30.5.1 Cement

White Portland cement is made of selected raw materials containing negligible amounts of iron and manganese oxides, as these materials project a gray color. White cements have inherent color and strength-development characteristics depending on their source; some have a buff or cream undertone, and others have a blue or green undertone. Cement of the same type and brand and from the same mill should be used throughout the entire job to minimize color variations. Color variations in a gray cement matrix are generally greater than those in matrices made with white cement. A gray color may be projected by using white cement with a black pigment or a blend of white and gray cement. Uniformity normally increases with increased percentages of white cement. Gray cement is dominant and will have much

FIGURE 30.5 Mock-up panels for USAA regional office in Tampa, Florida; architect, Spillis Candela & Partners, Inc., Coral Gables, Florida.

greater color variation than white cement with an added black pigment. Plastic or stainless steel trowels should be used for finishing architectural concrete to minimize the danger of staining or darkening the concrete. Trowel marks or surface burns can be minimized by troweling while the concrete surface is moist or by keeping the trowel wet during finish operations (Freedman, 1968, 1969).

30.5.2 Aggregates

The choice of aggregates can have a considerable effect on the finish color of white, buff, or light-toned concrete. The choice of fine and coarse aggregate should be based on a visual inspection of the samples and the mock-up. These samples would have the proper matrix and be finished in the same manner as planned for construction. The method used to expose the aggregate in the final product influences the final appearance. Sandblast textures will generally dull the appearance of the coarse aggregate. All coarse and fine aggregates should be from the same source for the entire project. Normally, aggregates will be selected for exposed architectural purposes and specified in the contract documents as to source, size, and color. Aggregates should have proper durability and be free of staining or deleterious materials. They should be nonreactive with cement, have a proven service record or satisfactory results from laboratory testing, and have the particle shapes (rounded rather than slivers) required for good concrete and appearance. When angular aggregates, such as small-size granites, are specified, the contractor should inform the architect and owner that they will produce greater color variations, some pour lines, and increased surface blemishes such as bug holes.

Where the color depends primarily on the fine aggregates, gradation control is required. For fine aggregates purchased in bulk, the percentage of fine particles passing the No. 100 sieve should be limited to no more than 5%. This may require double washing and a secondary screening, but the premium for this can be justified by the increased uniformity of color. With a light to medium exposure, a uniform color appearance may be obtained by using crushed sand of the same material as the coarse aggregate; however, for reasons of workability, a percentage of natural sand is always desired in a concrete mix. When maximum whiteness is desired, a natural or manufactured opaque white or light yellow sand should be used. Most naturally occurring sands lack the required whiteness, and the contractor or precaster must look to the various manufactured aggregates for the white base desired. Generally, these consist of crushed limestone (dolomite, calcite) or quartz and quartzite sands.

Coarse aggregates are selected on the basis of color, hardness, size, shape, gradation, method of surface exposure, durability, cost, and availability. Colors of natural coarse aggregate vary considerably according to location and geological classifications. Coarse aggregates should be reasonably uniform in color. Light and dark coarse aggregates require caution in blending for good distribution and color uniformity in adjacent concrete. Extreme color differences between fine and coarse aggregate or between the aggregates and matrix should be avoided. Often a pigment can be added to the matrix to more closely match the color of the aggregates. Extreme color differences between the aggregates and matrix will create uniformity problems and possibly lead to aggregate transparency. The use of closely graded fine and coarse aggregate in a gap-graded combination often results in less segregation and produces a more uniform finish. While gap grading is an established and well-proven practice, it should not be carried to extremes. Extreme gap grading may lead to separation of the paste and aggregates and thus create uniformity problems. This can be particularly true when dense, hard surface forms are used in combination with high-frequency

FIGURE 30.6 Separation of the paste and aggregates when using high-density forms and high-frequency vibrators. Dark paste lines are evident after sandblasting.

FIGURE 30.7 Pour lines on interior beams where the concrete was placed during hot weather. Higher dosages of admixtures could have been used to minimize the possibility of early set leading to pour lines.

vibration (Figure 30.6). The amount of fines, cement, and water should be minimized to ensure that shrinkage remains within acceptable limits and that surface absorption will be low enough to maintain good weathering qualities. The durability of the concrete would normally not be affected by any degree of gap grading as long as proper concrete cover is maintained over the reinforcement.

30.5.3 Water

Mixing water should be clean and free from oil, acid, iron or rust (which may cause staining), and injurious amounts of vegetable matter, alkalis, or other salts. Almost any natural water that is drinkable and has no pronounced taste or odor is satisfactory. Warm water may tend to cause false set or shorten the working time of the mix. Chilled water or use of ice may retard the set or make mixing more difficult.

30.5.4 Admixtures

Water-reducing and set-controlling admixtures have been found to be effective with respect to water reduction and strength increases when used with Portland cements of low tricalcium aluminate (C_3A) and alkali content. Architectural concrete dosages are in excess of those generally used for structural concrete and may require up to 50% more than the usual recommended minimum. Admixtures are important in architectural concrete for workability, to assist in placement, and to minimize the possibility of pour lines occurring in warm weather due to early set (Figure 30.7). An increase in cement fineness or a decrease in cement alkali content generally increases the amount of air-entraining admixture required for a given air content. High-range water-reducing admixtures (HRWRAs) may alter the air-void system of air-entrained concrete. Typically, the void-spacing factors are higher than in normal air-entrained concrete. This void spacing is caused by an increase in the average bubble size and a decrease in the specific surface compared to an air-entrained concrete without an HRWRA. In such cases, the dosage of the air-entraining agent would be adjusted to compensate for this effect. In some cases, a complete loss of air may occur when using HRWRA. It may be necessary to change to another HRWRA or use a different air-entraining agent. Certain air-entrained admixtures may be more effective with certain HRWRAs, in the production of adequate air entertainment. When HRWRA are used, there can be an increased tendency for segregation in the concrete mix, particularly when gap-graded aggregates are used. All admixtures should be tested to ensure their compatibility. The use of calcium chloride as an admixture may contribute to the corrosion of metals and darkening, mottling, and discoloration of the concrete surface. Its use is not recommended for architectural concrete. In spite of the use of such terms as “chloride

free,” no truly chloride-free admixture exists, as admixtures often are made with water that contains small but measurable amounts of chloride ions. If, when using the available information on the admixture and the proposed dosage rate, it is calculated that the chloride ion limitation will be exceeded, alternative admixtures or procedures should be considered. When coloring pigments are added to the concrete mixture, the amount should be less than 5% of the weight of the cement. Amounts in excess of 5% seldom produce further color intensity, while amounts greater than 10% may be harmful to the concrete quality. For any coloring agent, it is important to have tests or performance records that indicate color stability in concrete.

30.5.5 Mixture Design

Architectural concrete should provide both proper workability required for consolidation and adequate strength for the given type of concrete. The architect should specify the parameters of concrete performance requirements. A design strength for concrete should be determined by the engineer, based on in-service requirements, while not forgetting construction and, in the case of precast, handling and erection considerations. A concrete mix designed for purely structural reasons or for light acid-etched or very light sandblast texture is normally fully (continuously) graded, which means that it contains all the sizes of aggregates (below a given maximum) in amounts that ensure an optimum density of the mix.

Gradation standards for gap-graded mixes vary widely. The use of one sieve size or narrow size range for coarse aggregate, with a small percentage of concrete or masonry sand for workability, results in a more uniform distribution of exposed aggregate when texture is desirable. Gap-graded aggregates in which the coarser particles of sand and finer particles of coarse aggregate are omitted can produce a surface with greatly reduced bug holes provided proper consolidation is used. Lower sand content can result in greater color variations and aggregate transparency when dark-colored coarse aggregates are used. Good concrete mix design aims to produce uniformity of color, avoid segregation, and minimize other surface blemishes. This type of mix is not necessarily the same as that used in standard structural concrete. When a contractor accepts the concrete mix design for architectural concrete, whether it be from the architect or a local laboratory, the contractor implies that he is capable of using that mix proportion of specific materials to produce concrete with good workability and of adequate strength that will also produce concrete surfaces with an absolute minimum of surface blemishes. This is a big responsibility and should not be assumed by the contractor until after mock-ups are completed and approved.

The ratio of fine aggregate to coarse aggregate by weight should be 1:2:5 to 1:3:5 in gap-graded mixes. The fine aggregate is usually masonry sand. With high cement content concretes, coarsely graded sands may be satisfactory because the cement helps provide the needed fines for workability. With low cement contents (under 564 lb/yd³), the fine aggregate particles are necessary for good workable mixtures. Mixtures with higher cement contents can generate substantial heat. It is sometimes necessary to place thermal curing blankets around the forms to prevent rapid cooling of the exterior of the concrete and induce thermal cracks in the concrete due to temperature differentials.

Self-consolidating concrete (SCC) is becoming increasingly viable in the concrete market, particularly in precast plants. Although SCC requires increased emphasis on quality control and improved materials, the benefits derived from a reduction in air bubbles, decreased need for skilled placing labor, and improved product consistency can more than outweigh the increased cost of the mix and process. Not all locations can successfully produce SCC on a consistent basis, however. Selection of SCC as part of the process must be based on locally available materials, quality control capabilities, environmental constraints, and a proven track record on the part of the concrete producer.

30.5.5.1 Smooth Texture

For adequate consolidation of continuously graded concrete, the desirable amount of air, water, cement, and fine aggregate (i.e., the mortar fraction) is about 50 to 65% by absolute volume (45 to 60% by weight). Rounded aggregates, such as gravel, require slightly lower values, and crushed aggregate requires slightly

higher values. Fine aggregate content is usually 35 to 45% by weight or volume of the total aggregate content. Aggregate fines below a No. 50 (3-mm) screen should not be in excess of 5%. If suitable form materials, release agents, and placing techniques are used, air voids on a surface can be reduced in size and number to an acceptable level.

30.5.5.2 Very Light to Light Texture

An acid wash or very light sandblast texture often uses a maximum coarse aggregate size of 3/8 in. (9.5 mm). The very light texture is sometimes referred to as an *Indiana limestone finish*. Aggregates may be continuous or gap graded.

30.5.5.3 Medium Texture

During the process of removing the cement/sand matrix from the exposed surfaces, coarse aggregate in the middle size range may not be able to adhere to the remaining concrete surface, particularly if the particle shape is elongated, sharp, or flat. If these sizes are not eliminated from the mix, the percentage of the surface covered by the matrix (sand and cement) may be too large and the aggregate distribution too uneven to provide a good surface appearance. The maximum size aggregate in gap-graded mixes should be 1 in. (25 mm), as mixes with larger sizes of aggregate are extremely difficult to place. This is because the larger particles seldom move from their original position even with heavy vibrator effort, and they are more prone to segregation.

30.5.5.4 Heavy Texture

For a heavy exposed-aggregate finish using an aggregate of 3/4-in. (19-mm) maximum size, the No. 4 to 3/8-in. (4.75- to 9.5-mm) particles could be omitted without making the concrete unduly harsh or liable to segregation. To achieve a gap between the 1/3-in. (8-mm) size and the No. 8 (2.36-mm) size, it is advisable to limit the amount of material passing the 3/8-in. (9.5-mm) sieve to between 0 and 10%. A typical fine aggregate should have 100% passing the No. 8 (2.36-mm) sieve and from 0 to 10% passing the No. 100 (150-µm) sieve. Although a sand gradation typical for concrete can usually be used, in heavy exposed-aggregate mixes, it is advantageous in some cases to use a masonry or industrial sand for the fine aggregate where most of the particles pass a No. 8 (2.36-mm) sieve. The sand should have a fineness modulus of 2.4 or less. A greater explanation of mix requirements for different textures may be found in reference material, such as the *PCI Manual for Quality Control for Plants and Production of Architectural Precast Concrete Products* (PCI, 1996). Concrete mixtures for heavy exposed-aggregate finishes usually contain more coarse aggregate than typical concrete mixtures. These mixes must usually be placed at under a 5-in. (125-mm) slump.

30.5.6 Wood Sealers

With wood forms, release agents should generally be used over a sealed form surface. Sealers can minimize nonuniformity in surface finishes and extend the number of uses of the wood forms. Types of wood sealers are lacquer, epoxy, polyester, and polyurethane. Wood sealers help maintain a uniform color in the concrete. The lower the water/cement ratio, the darker the concrete surface, so if the absorption of the form is not uniform the concrete will vary in color uniformity. Sealed, nonabsorbent forms prevent moisture loss and result in finishes that are uniform in color but lighter than those cast in absorbent forms. Formwork surfaces must be dry and free from dirt, grease, or other impurities before form sealers are applied. The sealers should be applied to wood when it is new and unoiled. Before it can be sealed, the surface must be sanded to remove all raised grain and rough areas, and all holes or imperfections must be filled with a waterproof filler. For some sealers, minimum temperatures are stated below which they must not be applied. An appropriate drying or curing time should be allowed. The manufacturer's instructions regarding application of the sealer must be followed, and the work should be done by a skilled worker.

30.5.7 Release Agents

Release agent selection should include investigation of the following factors (ACI Committee 303, 1974):

- Compatibility of the agent with the form material, form sealer, and admixtures in the concrete mix (because of the rapid loss of slump, most superplasticized concrete requires a smooth, frictionless surface along which the concrete can easily move)
- Possible interference with the later application of sealants, sealers, or paints to the form contact face
- Discoloration and staining of the concrete face
- Amount of time allowed between application and concrete placement and the minimum and maximum time limit for forms to stay in place before stripping (release agents may require a curing period before being used; if the concrete is too fresh when the agent is applied, some of the release agent will become embedded in the concrete)
- Effect of weather and curing conditions on ease of stripping
- Uniformity of performance
- Conformance to local environmental regulations regarding the use of a volatile organic compound (VOC)-compliant form release agent

Release agents or form oils are still probably the leading cause of discoloration on architectural concrete. Today, many suppliers can offer a 100% nonstaining type if the contractor or precast manufacturer requests it. The safest approach is to evaluate the three or four products being considered by casting small-scale trial batches of concrete in forms treated with the various products. Release agents improperly applied will cause as much color variation as any other factor known. Generally, the thinner the amount of the coating, the better the surface finish. Applying too much of the release agent can cause excessive surface dusting on the finished concrete. Discoloration may be caused by excessive use or uneven application of the release agent. Bug holes can be expected where release agents are allowed to puddle on the form or mold or allowed to collect in the many nooks and crannies of a mold. Great care should be taken to see that the equipment used for applying the coating is clean (PCI, 1996).

Coating thickness can be controlled by removing excess amounts with a clean cloth. A good rule of thumb is that, if rubbing a finger across the surface results in a deposit of the freshly applied release agent, then too much is present. One brand or batch of form-release agents should be used throughout a project. Information should also be obtained from the release agent manufacturer as to the kind of form surface for which the product is intended as well as the rate of spread and the proper method of application.

Generally, water-based or emulsion-type release agents cannot be used in very cold weather because they might freeze. Even at temperatures slightly above freezing, some water-based products thicken enough to produce more bug holes and reduce performance. Also, a form face coated with a water-based agent should be protected from rain; otherwise, some of the agent can wash off and it may be necessary to apply a second coat to a dry surface before placing concrete. For steel forms, release agents should contain a rust inhibitor and be free of water. Rough surfaces on steel forms may be conditioned against sticking by rubbing on a liquid solution of paraffin in kerosene, or the molds may be cleaned and oiled with a nondrying oil, then exposed to sunlight for a day or two (PCI, 1996).

To reduce color changes, a suitable release agent should be applied for the first and all subsequent uses of glass-fiber-reinforced plastic molds or plastic form liners. An oil-based emulsion or high-quality household wax containing carnauba wax are preferable. Unsaturated oils, ketones, esters, acids, toluol, toluenes, xylenes, or halogenated solvents should be checked for compatibility with the plastic materials. If curing requires high temperatures, a silicone release agent should be used. Concrete molds will require a release agent consisting of light-colored petroleum oils or oil emulsions. The concrete surfaces may be coated with one or two coats of epoxy resin and then waxed. A saponifiable oil should not be used as a release agent.

Rubber or elastomeric liners may be coated with a thin film of castor oil, vegetable oil, lanolin, or water-emulsion wax. Mineral oil, oil-solvent-based release agents, or paraffin wax should not be used on rubber or elastomeric liners as the hydrocarbon solvent will soften the rubber. The rubber or elastomeric

supplier's recommendation should be carefully followed. Plastic foam molds are generally lightly sprayed with castor oil, petroleum jelly thinned with kerosene, or paraffin oil. As the concrete surface texture increases, the influence of the release agent becomes less important. It is desirable that the brushes or spray equipment be clean and that no laitance or build-up of concrete is on the form surface before the release agent is applied.

30.6 Color and Texture

30.6.1 Color

Architectural concrete can be cast in almost any form or texture to meet the aesthetic and practical requirements of modern architecture. Combining color with texture accentuates the natural beauty of the aggregates. Aggregate colors range from white to pastel to red, black, and green. Natural gravels provide a wide range of rich earth colors, as well as shades of gray. Color selection should be made under lighting conditions similar to those under which the architectural concrete will be viewed. Muted colors look best in subdued northern light. In climates with strong sunlight, much harder and brighter colors can be used with success. The water/cement (w/c) ratio affects the color; the more water (higher w/c ratio), the lighter the color even with the same cements. Richer mixes are darker than lean mixes. The common slump test is the usual measure of concrete consistency. Poor concrete mix control and wide variations in slump will produce different shades of color in any project. Variations in aggregate gradation can cause slump variations even when the w/c ratio remains constant. Color differential will follow variations in the w/c ratio regardless of slump. Good field control involves both aggregate gradation and slump control. Superplasticizers can change workability without adding extra water. If superplasticizers are used on one concrete placement, they should be used on all.

Color and color tone represent relative values. They are not absolute and constant but are affected by light, shadows, density, time, and other surrounding or nearby colors; for example, a concrete surface with deeply exposed opaque white quartz appears slightly gray. This is due to the fact that the shadows between the particles "mix" with the actual color of the aggregate and produce the graying effect. These shadows in turn affect the apparent color tone of the matrix. Similarly, a smooth concrete surface will change in tone when striated. A white precast concrete window unit with deep mullions will appear to change tone when bronze-colored glass is installed. A change in color tone is constantly going on as the sun travels through the day. A clear sky or one that is overcast will make a difference, as will landscaping and time. And last, but by no means least, in large city and industrial environments, air pollution can cause the tone to change. This is particularly noticeable when additions are planned to existing buildings built 10 or more years previously (Figure 30.8). The ease of obtaining uniformity in color is directly related to the ingredients supplying the color. Whenever possible, the basic color should be established using colored fine or coarse aggregates (depending on depth of exposure) and pigments to blend the aggregates and matrix. Extreme color differences between aggregates and matrix should be avoided. In all cases, color should be judged from a full-sized sample that has the proper matrix and has been finished in accordance with planned production techniques. The sample should be assessed for appearance during both wet and dry weather. The difference in tone between wet and dry concrete is normally less when white cement is used. In climates with intermittent dry and wet conditions, drying out periods often produce blotchy appearances on all-gray surfaces. On the other hand, dirt (weathering) will normally be less objectionable on gray concrete. These comparisons are based on similar water absorption or density of white and gray concrete.

30.6.2 Texture: Cast-in-Place and Precast

Textures allow the natural attributes of the concrete ingredients to be expressed, provide some scale to the mass, express the plasticity of the concrete, and normally improve its weathering characteristics (PCI, 1989). A wide variety of textures is possible, ranging from smooth or polished to a deeply exposed tooled

FIGURE 30.8 Precast addition over 15 years later using the same cement, aggregates, and mix design.

or bushhammered finish. As a general rule, a textured surface is aesthetically more satisfactory than a smooth surface because to a very large extent the texture of the surface camouflages subtle differences in texture and color of the concrete. Exposed-aggregate surfaces may be achieved by removing surrounding paste through chemical processes (retarders or acid etching) or mechanically (abrasive blasting, honing and polishing, or tooling). Each method will uniquely influence the appearance of the exposed surface. Different degrees of exposure by any of these methods are defined as follows:

- *Light exposure.* Only the surface skin of cement and some sand are removed to expose the sand and the edges of the closest coarse aggregate. Matrix color will greatly influence the overall panel color.
- *Medium exposure.* Further removal of cement and sand has caused the coarse aggregate to appear visually to be approximately equal in area to the matrix.
- *Deep exposure.* Cement and fine aggregate have been removed from the surface so the coarse aggregate becomes the major surface feature.

A currently popular but very difficult texture is one that is much lighter than the above-referenced light exposure. This texture could be referred to as a brush exposure or a texture similar to Indiana limestone. Indiana limestone results can be best obtained by blending yellow and black sands in the concrete mix design to give a veining effect. This very light texture is difficult to obtain with either acid wash (must use a very diluted solution) or a single-pass sandblast (must use a reduced nozzle pressure of 50 to 60 psi). Brush-blast exposure will expose the surface skin of the cement and part of the sand surface. No coarse aggregate is exposed.

30.6.2.1 Smooth

The smooth or as-cast texture is accepted the way it appears when the forms are removed or when the precast unit is stripped from the mold. Construction of any smooth as-cast surfaces should be approached with caution by the contractor. Even the East Building National Gallery of Art in Washington, D.C., designed by I.M. Pei and Partners, was not purely a smooth as-cast texture. The contractor, Chas H. Tompkins Co., scrubbed the exposed concrete surface with a weak acid solution to remove construction stains and environmental grime. This gave a slightly weathered look to the basically as-cast concrete surfaces.

A smooth off-the-form finish may often seem to be the most economical, but it is perhaps the most difficult finish to do well, as the color uniformity of gray, buff, or pigmented surfaces is extremely difficult to achieve. The cement exerts the primary color influence on a smooth finish because it coats the exposed surface. In some instances, the sand may also have some effect. Initially, this is unlikely to be significant

unless the sand contains a high percentage of fines or is itself highly colored. As the surface weathers, the sand will become more exposed, causing its color to become more pronounced. The color of the coarse aggregate should not be significant, as it normally is not exposed to view unless the particular unit requires extremely heavy consolidation. Under this circumstance, some aggregate transparency may occur, causing a blotchy, nonuniform appearance (PCI, 1996).

Although a uniform graded concrete mix can be used with an as-cast finish, its w/c ratio should be controlled. Concrete slumps should be held in the range of $3 \pm 1/2$ in. and never over 4 in. Good consolidation techniques and thorough blending of lifts are extremely important. Although the use of concrete pumps is sometimes possible with this type of finish, the mix should not be oversanded or given additional water to facilitate the use of a pump. Oversanding greatly increases the possibility of segregation, resulting in noticeable surface variations. Aggregate transparency, or *shadowing*, is a condition in which a light-colored, formed concrete surface is marked by dark areas similar in size and shape to particles of dark or deeply colored coarse aggregate in the concrete mix. When encountered, it usually appears on smooth surfaces (Shilstone, 1972b).

The formwork for smooth-surfaced concrete is perhaps the most critical and the most difficult to control of any type of formwork encountered for cast-in-place or precast concrete, particularly where large single-plane surface areas are involved. Any imperfection in the surface of the form or any misalignment is immediately apparent and becomes the predominant factor in the character of the surface. Impervious surfaces such as plastic liners, steel, overlaid plywood, or fiberglass-surfaced plywood will usually result in a lighter color and more uniform appearance if joints have been properly prepared to eliminate leakage. In general, the joints of the materials used to construct the casting surfaces are difficult to hide unless rustications are used.

The smooth cement film on the concrete may be susceptible to surface crazing (fine and random hairline cracks) when exposed to wetting and drying cycles. This is, in most cases, a surface phenomenon and will not affect structural properties or durability. In some environments, crazing will be accentuated by dirt collecting in the minute cracks. This will be more apparent in white than gray finishes and in horizontal more than vertical surfaces. When air voids of a reasonable size, 1/8 to 1/4 in. (3 to 6 mm), are encountered on return surfaces, it may be desirable to retain them rather than filling and sack rubbing them. Color variations can occur when sacking is performed. If smooth surfaces are "to be produced without additional surface treatment after stripping, except for possible washing and cleaning," the following precautions should be considered:

- Pay attention to detailing with provisions for ample draft, proper edges and corners, rustications at form edges, and suitable water drips and other weathering details.
- Construct forms or molds so imperfections will not be mirrored in the units. The use of plastic molds or liners with a matte finish or fiberglass-overlaid plywood, which is smooth but not glossy, will help reduce crazing tendencies.
- Use the same mold release agent throughout construction, and apply it under as nearly identical conditions as possible each time. (Some release agents help reduce the crazing tendency by breaking the contact with the glossy surface of the form.)
- Use concrete mix designs that combine a minimum cement content and a constant, low w/c ratio with high density to minimize crazing, entrapped air voids, and color variations. The mix should be fully graded with no more than 5% aggregate fines passing a No. 50 (300-mm) sieve.
- Use proper consolidation and curing to minimize nonuniformity of color, which shows easily on smooth concrete surfaces, particularly with gray concrete mixes. Uniform curing with minimum loss of moisture from the smooth surface will help minimize crazing tendencies.
- Minimize chipping or other damage because smooth finish repairs are difficult to perform in terms of texture and color match.

Many of the aesthetic limitations of smooth concrete may be minimized by the shadowing and depth provided by profiled surfaces (fluted, sculptured, board finishes, etc.) that subdivide the panel into smaller surface areas by means of vertical and horizontal rustications, or by the use of white cement.

30.6.2.2 Sand or Abrasive Blast

Sand or abrasive blasting of surfaces can provide all three degrees of exposure: light, medium, or deep (PCI, 1996). Generally, the technique is used when a light exposure is desired, because sandblasting costs increase with the depth of exposure. Sand or abrasive blasting of surfaces is suitable for exposure of either large or small aggregates. Uniformity of depth of exposure between panels and within panels is essential in abrasive blasting, as in all other exposed-aggregate processes, and is a function of the skill and experience of the operator. As much as possible, the sandblasting crew and equipment used should remain the same throughout the job. Different shadings and, to some extent, color tone will vary with depth of exposure.

The degree of uniformity obtainable in a sandblasted finish is generally in direct proportion to the depth of sandblasting. A light sandblasting may look acceptable on a small sample, but uniformity is rather difficult to achieve in a full-size wall or precast unit. A light sandblast will emphasize visible defects, particularly bug holes, and reveal defects previously hidden by the surface skin of the concrete. The lighter the sandblasting, the more critical the skill of the operator, particularly if the units are sculptured. Small variances in concrete strength at the time of blasting may further complicate results. Sculptured units will have air voids on the returns that might show strongly in a light-sandblasted texture. If such air holes are of a reasonable size, 1/8 to 1/4 in. (3 to 6 mm), it is strongly recommended that they be accepted as part of the texture because filling and sack rubbing may cause color variations. Blasting will cause some etching of the face of the aggregate, and the softer aggregates will be etched to a greater extent with heavier exposures. Sandblasted aggregates lose their sharp edges. Blasting of the aggregate surface is more noticeable on dark-colored aggregates that have a glossy surface texture. Sandblasting dark-colored aggregates will produce a muted or frosted effect, which tends to lighten the color and subdue the luster of the aggregate (Figure 30.9). The depth of sandblasting should also be adjusted to suit the aggregate hardness; for example, soft aggregates might be eroded at the same rate as the mortar.

For medium or deep exposure with a sandblasted finish, retarders may be used initially and the matrix removed by sandblasting to obtain a matte finish. The selected retarder strength should only give 50 to 75% of the expected reveal. This approach reduces blasting time and lessens the abrasion of softer aggregates. Using sandblasting to achieve the final texture allows for correction of any variations in exposure, so this method can result in a very uniform surface. Care should be taken to avoid nonuniform exposure that may be caused by the presence of soft and hard spots on the retarded surface. This is especially true and more noticeable on large, flat surfaces. Small, flat areas or surfaces that are divided by means of rustications will tend to call less attention to these texture variations. Because some aggregates change color after sandblasting, trials on sample panels using different abrasive materials are desirable to check the texture and color tone. As an additional step toward uniformity, the cement and sand color should be chosen to blend with the slightly bruised color of the sandblasted coarse aggregate, as the cement-sand matrix color will predominate when a light sandblast finish is desired. With a light sandblasting, only some of the coarse aggregates near the surface will be exposed, so a reasonable uniform distribution of such aggregates is not controllable.

The concrete mix used and the matrix strength at the time of blasting will affect the final exposure, as will the gradation and hardness of the abrasive. A good general rule in selecting an abrasive is that the particle size of the abrasive will attack a similar size particle in the concrete surface. Larger abrasive particles usually result in a rougher, more uniform matte appearance. Smaller abrasive particles typically result in a more variable luster finish. For a more uniform texture, spherical or nearly round abrasives with a close gradation should be used. Materials used in the blasting operation are washed silica sand, certain hard angular sands, aluminum carbide, blasting grit such as power plant boiler slag, carbonized hydrocarbon, crushed chat (a waste material from lead mining), and various organic grits such as ground shells, corn cobs, and rice hulls. For cleaning or light blasting of a surface, any of these abrasives will be adequate. For deep cutting, an abrasive grit should be used because of its speed of attack and cleaner surface appearance. Some types of colored abrasives impart color to the surface of the concrete. With certain gradation combinations, pressures, and volumes, impregnation of the abrasive into the surface can occur. If this happens, an abrasive of similar color to the matrix should be used. Impregnation of

FIGURE 30.9 Heavy abrasive, blasted, cast-in-place, gap-graded concrete texture on the Tennessee State Office Building in Memphis, Tennessee; architect, Roy Harover.

abrasive can be minimized by a change in the volume of material, its gradation, or the pressure being applied. Sandblasting may be done with dry abrasive in a stream of compressed air or water rings may be used to introduce water into the compressed air-sand stream at the nozzle. Sand also may be introduced into a high-pressure water washer. When using wet sandblasting, the abraded mortar should be continually washed off already sandblasted areas to prevent staining.

The inside diameter of the hose should be no less than 1-1/4 in. (32 mm) or four to six times the diameter of the nozzle orifice to keep the sand in continuous suspension while it travels through the hose. Too large a hose would reduce the velocity of media and air and would eventually plug the hose. Smaller diameter whip lines may be used for operator ease of handling. The nozzle at the end of the system is the most important element. The diameter of the nozzle and nozzle pressure should be determined by experimentation. A Venturi-type nozzle should be used to obtain a uniform blast pattern. Carbide or nitride nozzles should be selected for durability. Nozzle life depends on abrasive hardness and volume as well as the pressure and generally varies from 2 to 4 months.

The time when sandblasting should take place is determined by scheduling, economics, visual appearance desired, and hardness of the aggregate. The timing of blasting is not as critical as for other finish methods. The concrete matrix will be easier to cut in the first 72 hours after casting, but variable early concrete strengths may result in a more variable etch. As the concrete cures and gains strength, it becomes more difficult to blast to any appreciable depth, thus increasing the cost of the operation. Softer aggregates tend to abrade more when concrete strengths are high and the surface will have a duller appearance. In some cases, the higher costs of deferred blasting may be justified to avoid scheduling problems; however, all surfaces should be blasted at approximately the same age or compressive strength for uniformity of appearance.

When blasting, the operator should hold the nozzle perpendicular to the surface being blasted. Some operators will deviate slightly from this position as it seems to provide a better view of the work. The maximum deviation should be less than 15°, as too much deviation from the 90° angle will result in undercutting the coarse aggregate particles. Best results are obtained with the nozzle positioned from about 2 to 6 ft (0.6 to 1.8 m) from the element surface. The exact distance depends on the pressure used, the hardness of the concrete matrix, and the cutting ability of the abrasive. An experienced operator can quickly determine the nozzle position to produce the specified surface finish. Using a circular motion during blasting will minimize pattern marking.

30.6.2.3 Acid Etch

Acid etching of concrete surfaces can result in a pleasing fine sandy texture and retention of detail if the concrete mix and its consolidation have produced a uniform distribution of aggregate particles and cement paste at the exposed surface. The contractor should approach this finish very carefully. Vertical cast-in-place concrete exposed with acid can be an environmental problem. New equipment that uses high-pressure pumps and a controlled combination of acid and hot water has minimized the application problems. When using this equipment, runoff water is close to neutralized. Some local codes or concerned citizens may require complete containment of the acid residue runoff even though the acid parts per million are insignificant. This may involve construction of earth dams and a holding pond for the water prior to treatment. It has become increasingly difficult to perform any work requiring acid at job sites due to potential liabilities and environmental concerns. All personnel working with or near the acid application area will need protective gear and clothing to prevent injury from the spray. Prior to acid etching, all exposed glass and metal surfaces should be protected with acid-resistant coatings. These include vinyl chlorides, chlorinated rubber, styrene butadiene, rubber (not latex), bituminous paints or enamel, and polyester coatings. Architectural surfaces should be thoroughly flushed with large quantities of clean water immediately prior to the application of acid. Acid etching is most commonly used for light or medium exposure. Acid etching of concrete surfaces will result in a fine, sandy-textured distribution of aggregates and cement paste at the exposed surfaces. Concentrations of cement paste and under-and-over etching of different parts of a concrete surface or variations in sand color or content may cause some uniformity problems, particularly when the acid etching is light or used for large, plain surfaces. Carbonate aggregates (e.g., limestones, dolomites, and marbles) may discolor or dissolve due to their high calcium content. With lighter textures, the color compatibility of the cement and the aggregates becomes more important for avoiding blotchy effects. White or light colors are forgiving to the eye and increase the likelihood of a better color match from unit to unit. Gray is the worst color to select for uniformity. An acid-etch finish is more difficult to patch than many of the deeper texture finishes; however, minor air voids are fairly easy to grout and refinish. There is a minimum depth of etch that is required to obtain a uniform surface. To attempt to go any lighter than this will result in a blotchy panel finish. A minimum depth of etch will expose the sand and the very tip of the coarse aggregate approximately 1/16 in. (1 mm). It is difficult to achieve a totally uniform, very light exposure on a panel that is highly sculptured. This is due to the acid spray being deflected to other areas of the panel, particularly at the inside corners. This may be acceptable if the sculpturing creates differential shadowing. Prewetting the concrete with water fills the pores and capillaries and prevents the acid from etching too deeply, in addition to allowing all of the acid to be flushed after etching. Older dried concretes are likely to be more carbonated. Although the reactions of carbonates with the acid might not be much faster than those with other cement compounds, they cause greater efflorescence so the reaction is far more obvious and seems to go faster. Acid solutions lose their strength quickly once they come into contact with cement paste or mortar; however, even weak, residual solutions can be harmful to concrete due to the possible penetration of chlorides. Failure to completely rinse the acid solution off the surface may result in efflorescence or corrosion.

30.6.2.4 Retarders

Chemical surface retarders applied to formwork or sprayed on the top of horizontal concrete provide a nonabrasive process that is very effective in bringing out the full color, texture, and natural beauty of the

coarse aggregate. The aggregate is not damaged or changed by this exposure method. If exposing the bright, natural colors of the aggregate is the prime goal, exposing aggregate from retarded surfaces is one of the best ways to achieve this result. Surface retarders that are to be used to expose the aggregate should be thoroughly evaluated prior to use. A sample panel should be made to determine the effects created by the form or mold and concrete materials. This involves using the particular type of cement, aggregate (proportion determined by specified mix design), and selected release agent. Prolonged exposure of the forms coated with the retarder prior to placing the concrete should be avoided. Water should not contact the retarder on the form surface before the concrete is placed to prevent activation of the retarder. When using a retarder, the manufacturer's recommendations should be followed. Surface retarders can be applied by roller, brush, or spray, and care must be taken to ensure uniform application to the form surface.

The performance of the retarder will be influenced by chemistry of the individual cement, mix characteristics, temperature of the concrete, humidity, ambient temperature, characteristics of absorption of the forming material, and total water content of the concrete mix. It is important to consider protecting the treated form surfaces from weathering and ultraviolet rays before casting the concrete. Retarders function by delaying, not preventing, the set of a given amount of cement paste so the aggregate can be easily exposed. This concept will help in analyzing various mix designs for depth of retardation. If more sand or coarse aggregate is added to a mix with proper consolidation, there will be less cement paste per volume of material at the surface and thus a deeper exposure. Some retarders are effective for long periods of time, while others are active for only a few hours. Water contacting the retarder before the concrete is placed activates the action of the retarder prematurely and may result in a nonuniform surface.

The retarded concrete should be removed the same day that the forms are stripped using a high-pressure water blast through a fan nozzle. Any delay in removing the matrix will result in a lighter, less uniform texture. The stripping schedule must be coordinated with that of the work force responsible for form removal so there will not be long periods between form removal and concrete finishing. For a large project, preliminary tests should be performed before planning the casting to determine the most suitable finishing time. The timing of the surface finishing operation should be consistent each day, as some retarders cease to delay the hardening process as the product cures.

30.6.2.5 Tooled or Bushhammered Finish

A tooled or bushhammered finish is usually achieved by casting concrete against smooth or specially textured or patterned formwork. After removal from the form, the hardened concrete is treated mechanically to create the desired effect. Concrete made with most aggregates can be tool finished, but materials that can be cut or bruised without shattering, such as calcareous limestone and igneous rocks, give results that find the widest acceptance. Aggregate particles of 3/8 in. and smaller are more important for scaled and tooled surfaces. The coarser aggregate particles are more important for jackhammered surfaces. Some jackhammered surfaces, where considerable depth of finish is desired, may only require forming practices similar to a good structural concrete. Mechanically fractured surfaces are prepared by one of four methods: scaling, bushhammering, jackhammering, or tooling, which includes reeding. These types of surface textures are described as *fractured* because the surface is prepared by striking the concrete with a tool, thereby mechanically removing part of the surface. Concrete may be mechanically spalled or chipped with a variety of hand and power tools to produce an exposed-aggregate texture. Pneumatic or electric tools may be fitted with a comb chisel, crandall, or multiple pointed attachments. The type of tool will be determined by the surface effect desired. Hand tools may be used for small areas, corners, and restricted locations where a power tool cannot reach. Basically, all methods of tooling remove a layer of hardened concrete matrix while fracturing the larger aggregates at the surface. Surfaces attained can vary from a light scaling to a bold, deep texture achieved by jackhammering with a single pointed chisel.

Orientation of the equipment and direction of movement should be kept uniform throughout the tooling process as tooling produces a definite pattern on the surface. Variations caused by more than one person working on the surface may occur with this type of finish. Care should be exercised to avoid exerting excessive pressure on the tool, especially when starting, so as not to remove more material than either necessary or desirable.

FIGURE 30.10 Heavy jackhammer surface on Southern Bell Tower in Atlanta, Georgia; architect, Skidmore, Owings, and Merrill, Chicago.

Bushhammering at outside corners may cause jagged edges. If sharp corners are desired, bushhammering should be held back from the corner. It is quite feasible to execute tooling along specific lines. If areas near corners are to be tooled, this must normally be done by hand as power tools will not reach into inside corners. Chamfered corners are preferred with tooled surfaces. With care, a 1-in. (25-mm) chamfer may be tooled. Scaling is the lightest texture in bushhammered finishes. It is achieved by passing a triple-pronged scaler (originally developed to remove scale from steel prior to pointing) singly or in gangs over the surface to remove only a thin skin. A single-head scaler is lightweight and can be readily manipulated by one person. No texture as such is brought out by this technique, although some aggregate is exposed and fractured in the process. Under certain conditions, almost the same result can be achieved by light abrasive blasting.

Jackhammering should be done when the matrix has reached a strength approximating that of the coarse aggregate to fracture both the mortar and the coarse aggregate. If hammering is initiated too soon, the tool merely removes the matrix and the coarse aggregate does not fracture. Sometimes the coarse particles are knocked out, leaving blank spaces. If jackhammering is to be performed at a time when the matrix is softer than the coarse aggregate, a chisel-type tool should be used. This tool has a tendency to fracture across the aggregate, while a pointed tool has a tendency to dig into the matrix and not fracture the coarse aggregate. On the other hand, when a concrete becomes very hard the pointed tool does a superior job. Because jackhammering accentuates the presence of coarse aggregate, a higher than normal coarse aggregate content may be desirable (Figure 30.10) (PCI, 1996).

Although a dense, fully graded concrete mix is desirable, bushhammering may be successfully applied to gap-graded concrete. Natural gravels are inclined to shatter, leading to bond failure and loss of aggregate particles when bushhammered. Aggregates such as granite and quartz are difficult to bushhammer uniformly because of their hardness and may fracture into rather than across the concrete surface. Aggregates such as dolomite, marble, calcite, and limestone are softer and more suitable for bushhammered surfaces.

To prevent loosening of the aggregate, a compressive strength of 4000 psi (28 MPa) is recommended. In many cases, better uniformity may be obtained when the concrete is allowed to age for 14 to 21 days and the surface is dry. Exposing the aggregate by tooling requires trained operators to produce a uniformly textured surface, especially when large areas are to be textured. A hammered rib (or fractured fin) finish may be produced by casting ribs on the surface of the unit and then using a hammer or bushhammer

tool to break the ribs and expose the aggregate. The ribs may be hammered from alternative sides, in bands to obtain uniformity of cleavage, or randomly, depending on the effect required. There should be a definite plan, even with a so-called random pattern, because an uneven shading effect may be produced unless care is exercised. Tooling and bushhammering remove a certain thickness of material, 3/16 in. (5 mm) on average, from the surface of the concrete and may fracture particles of aggregate, causing moisture to penetrate the depth of the aggregate particle. For this reason, the minimum cover for the reinforcement should be somewhat greater than normally required. It is recommended that 2 in. (50 mm) of concrete cover be specified (prior to tooling). As a cutting head becomes worn, it should be replaced. Because the texture varies with the condition of the cutting surface, a new head should not be worked next to an area tooled with an old one. Small irregularities in the finished surface can be worked out with further tooling.

30.6.2.6 High-Pressure Water Jet Blasting

Blasting with high-pressure water instead of sand has received limited use in architectural concrete, particularly with precast concrete. Restrictions on sandblasting in many areas of the country are sure to increase the spread of this method of exposing aggregates at the surface. It uses only water, no harsh chemicals, so there is no pollution or health risk from burns or fume inhalation. Under special situations or where environmental restrictions exist, the water spray can be mixed in the nozzle with a fine spray of sand. Units are available with more than 10,000 psi of pressure, although usually 5000 psi is sufficient for aggregate exposure. Considerable splatter can develop, which requires that adjacent surfaces be protected. High-pressure water jets are used in combination with air to expose aggregates. The proper time of application must be determined for each concrete and its curing condition to obtain the desired amount of reveal without loosening the aggregate. The strength of concrete for high-pressure water washing is usually 1500 psi. It is important for the strength of concrete to be approximately the same when exposing the aggregate on different concrete placements. This method can be used with or without surface retarders (ACI Committee 303, 2004). Regardless of whether or not retarders are used, exposure should begin immediately after forms are stripped. Each equipment operator should be trained on a sample test area. All operators should be protected by rubber wet suits and goggles. They should wear rubber steel-tipped boots with clamp-on instep guards. These are required because the jet has enough force to cut through rubber into the flesh. A dead-man trigger on the gun automatically shuts off the water jet if the gun is accidentally dropped.

30.6.2.7 Form Liners

An almost unlimited variety of attractive patterns, shapes, and surface textures can be achieved by casting concrete against wood, steel, plaster, elastomeric, plastic, or foam plastic form liners. These form liners can be attached to or incorporated into the form itself. Most form liners can be used with any forming system. They are particularly useful in large heavy-duty gang form sections because the joints can be permanently aligned and sealed. Architects specify patterned concrete surfaces for the aesthetic interest generated by the play of light and shadow or to economically simulate the traditional patterns of brick, stone, and wood. Adding texture with a patterned form liner helps hide color variations and makes bug holes and other surface blemishes less noticeable. Defects due to leakage at form joints and poorly consolidated concrete also are less noticeable in patterned concrete (Hurd, 1993).

Material selection of the form liner should depend on the amount of usage and whether or not the pattern has undercut (negative drafts). The choice of liner materials may depend on whether the work is cast-in-place or precast. Thin sheets that serve well on horizontal forms may wrinkle and sag in vertical forms unless they are carefully attached. Thicker layers of liner material are more suitable for vertical surfaces. Vertical liners also must withstand the lateral pressure of concrete. This may call for control of concrete placing rates and added support for a contoured liner. The method of attaching form liners should be studied for the resulting visual effect. Form liners should be secured in forms by gluing or stapling, rather than by methods that permit impressions from nail heads, screw heads, rivets, or the like to be imparted to the surface of the concrete, unless desired. Where staples are used, they should be driven by a power stapler to ensure sufficient driving force. Staples should be aligned in a direction

consistent with the pattern to be imparted to the concrete. Staples should be spaced close enough to hold the liner securely in place. Where adhesives are used, particular attention should be given to following manufacturer's recommendations regarding adhesive cure period, ambient temperature, and moisture (Ford, 1982). Protection from the weather is essential. Attempts should be made to camouflage inequalities to within the pattern of the texture. The construction cycle, the probable number of reuses of the lined form, and the cost per use are other concerns in selecting a liner material. Trials should be made to determine the best time for stripping so the surface remains intact and liner reuse can be maximized.

Wood liners, whether used as boards, plywood panels, or nailed-on inserts, work well. Wood liner surfaces should be sealed to minimize discoloration of the concrete caused by differential absorption of mix water by the liner. The liner should then be lightly coated with a release agent prior to casting. Sandblasted wood, textured plywood, and rough-sawn lumber are often used for board-surface-textured finishes where concrete color variations and rough edges are acceptable. To prevent bowing of the boards, all sides should be coated with wood sealer by painting or immersion. Even with a sealer, some types of lumber may absorb moisture from the concrete. In other cases, natural sugars found in lumber such as pine may penetrate the sealer coating when the concrete is cast against the mold, retard the set of the cement at the surface, and cause a dusty, dark, blotchy effect. Fir is a preferred choice for board surface finishes due to its low sugar content. An effective method of sealing wood to eliminate any moisture transfer is to spray a few light coats of surface resin or urethane onto the wood. Care should be taken not to apply the sealer too thickly or the wood grain pattern will be lost. For molds with long casting durations, this process may have to be repeated. The weathering of the lumber can also affect the outcome of the concrete finish. If rough-sawn lumber is being used, it is important to produce samples to determine the effect the lumber will produce. The lumber selected should be purchased all at one time from one source to minimize the possibility of variations. Moisture leakage between pieces of lumber should be prevented, or a dark line will result from the change in w/c ratio. The joints may be sealed by using tongue-and-groove lumber. Closed-cell gasket material should be used at edges of the mold to prevent leakage. Wood liners may also be set or embedded in resin, which will eliminate the need for connectors that show as well as seal the edges against leakage (PCI, 1996).

Some experts believe porous or absorbent form liners offer a better chance to control bug holes than do impervious plastic liners, but the absorbency that provides this advantage can also pose problems. The more absorptive the form face, the darker the color of the concrete; however, as wood forms are reused and reoiled, their absorbency decreases. If patching or adjusting a much-used panel is required, the location of the new board or plywood will show up as a color difference that takes years to weather away (Figure 30.11). To avoid this problem with wood liners, up to one or two extra panels or gang forms should be made and kept in form rotation, then if one form panel or gang form is damaged it can be replaced with a form section already seasoned with use.

Elastomerics such as urethane and hot-melt vinyl are used to make liners flexible enough to permit vertical sides or some undercut areas. Elastomeric liners greatly facilitate removal from finished concrete surfaces in cases where other materials would be virtually impossible to strip. The design possibilities are almost limitless. Standard sheets are typically 4×8 to 4×12 ft, (1.2×2.5 to 1.2×3.7 m), but sizes up to 12×36 ft (3.7×11 m) can be special ordered to help minimize horizontal butt joints. Elastomeric materials should have a Shore A-2 hardness of 50 to 60 durometer and a minimum ultimate tensile strength of 600 psi (4.14 MPa). Elastomeric and rubber liners display gasketing characteristics and therefore achieve weep-free seamless joints. They also eliminate the need to cover the small slits cut in the liner for the fasteners. Elastomeric form liners may ripple unless there is a good bond to the base form. Edges of liners should be sealed to each other or to divider strips to prevent bleeding of cement paste. The sealant used should not stain the surface. Liners should not be butt-jointed without a demarcation feature to eliminate nonalignment of the texture. Liner size and module should be coordinated with panel joints, rustication strips, and blockout size.

Tough, wear-resistant elastomeric liners are relatively heavy and require good vertical support. They are usually attached to the form sheathing with adhesive, but some manufacturers supply these liners prebonded to plywood sheets. Elastomeric liners are sensitive to temperature change and may deform

FIGURE 30.11 Wood forms having varying degrees of absorbance as new sections have been added to gang forms.

significantly when exposed to surface temperatures above 140°F (60°C). Direct sunlight and the heat of hydration of the concrete can generate this level of temperature. Shade and temperature control of concrete during curing may be necessary. The liner should be checked for resistance to deterioration caused by oils commonly used as release agents and have rigidity sufficient to resist wrinkling. Solvent-based surface retarders should be checked to be sure they will not degrade the liner; if necessary, water-based or carried retarders should be used.

Several rigid liner materials such as ABS and polyvinyl chloride (PVC) come in sheets stiff enough to be considered self-supporting. High-impact polystyrene is also used to make rigid form liners. Readily available in 4 × 8-ft or 4 × 12-ft (1.2 × 2.5-m or 1.2 × 3.7-m) sheets, they can also be special ordered in lengths up to 30 ft (9.2 m) or more. Some manufacturers will supply interlocking joints at the edges of the panels that help hide vertical form joints. Rigid liners are well suited to ribbed patterns, but a detailed closure is required where the plastic flutes are cut at horizontal joints or openings. Some makers supply prefabricated closure pieces to solve this problem (Hurd, 1993). This material does not lend itself to intricate patterns, particularly with sharp corners, vertical sides, or undercuts (negative drafts). Basically, the material itself is inflexible. If it is broken, it is difficult to repair at the job site. Sheet plastics may require appropriate backup to resist movement, particularly for wide portions of liners with deep indentations. Movement can occur due to temperature changes caused by direct sunlight or the mechanical action of concrete placement. It is good policy to maintain a 10° draft on all indentation sides to prevent chipping and spalling during stripping operations. Keep all edges and corners rounded or chamfered. Relief may be more than 1 in. (25 mm) deep if the depressed area is sufficiently wide.

Foamed polystyrene or polyurethane liners create deeply revealed designs or blockouts. The preformed foam planks are easily cut to size and readily attached to the form. It is necessary to use a low-solvent contact glue that should dry before contact with the foam plastic is made or the solvent will dissolve the plastic. Liners made of polystyrene foam are used in large sheets like other liners or in smaller interlocking

modules designed to fit together with concealed joints. They typically are single use, as they are usually destroyed by the stripping process. Because of the one-time use factor, they are not cost efficient for large areas with a repetitive pattern. Repetitive form use requires a different type of liner. Rigid plastic forms can be molded to create complex liners with overall patterns or original works of art. Molded patterns have a surface skin that can be coated with a release agent. Strip the foam by hand or with air or water jets. If some of the plastic foam bonds to the concrete, it may be necessary to wirebrush or sandblast at reduced nozzle pressure to remove it.

Metal liners are available in various textures that can be combined with different types of fasteners to achieve an architectural effect. Liner joints should be at rustication strips or mold edges because leakage is difficult to prevent at butt joints. Combination finishes involving the use of more than one finishing method are almost infinite. One common example is the ribbed form liner and sandblasted finish.

30.6.2.8 Applied Coatings

Whenever concrete is to be coated or stained, only form-release agents compatible with the coating should be permitted, unless surface preparation is required to ensure good adhesion between the coating and the concrete. Coatings applied to exterior surfaces should be breathable (permeable to water vapor). The coating manufacturer's instructions regarding mixing, thinning, tinting, and application should be strictly followed. Whenever concrete is so smooth that it makes adhesion of the coating difficult to obtain, the surface should be lightly sandblasted, acid etched, or ground with silicon carbon stones to provide a slightly roughened, more bondable surface. Because of the vast differences in coating and stain types, brands, prices, and performances, knowledge of coating composition and performance standards is necessary for obtaining a satisfactory concrete coating or stain. To select proper coatings, the architect should consult with manufacturers supplying products of known durability and obtain from them, if possible, technical data explaining the chemical composition and types of coatings suitable for the job at hand. For high-performance coatings, proprietary brand-name specifications are recommended. The interior surface of exterior walls should have a vapor barrier (coating or other materials) to prevent water vapor inside the building from entering the wall.

30.6.3 Texture: Precast Only

30.6.3.1 Sand Embedment

Bold, massive, rocklike architectural qualities may be achieved by hand-placing 1 to 8-in. (25 to 200-mm)-diameter stones (cobbles or boulders), fieldstone, or flagstone into a sand bed or other special bedding material. The depth of the bedding material should keep the backup concrete 25 to 35% of the diameter of the stone away from the face. Extreme care should be taken to ensure that the aggregate is distributed evenly and densely on all surfaces, particularly around corners, edges, and openings. To achieve uniform distribution and exposure, all aggregate should be of one size gradation. Where facing materials are of mixed colors, their placement in molds should be carefully checked for the formation of unintended patterns or a local high incidence of a particular color. If the intention is to expose a particular facet of the stone, placing should be carefully checked with this in mind before the backup concrete is placed. The sand-embedment technique reveals the facing material and produces the appearance of a mortar joint on the finished panel. If a white or colored mortar joint is desired, a mortar consisting of one part white cement (plus pigment) to 2-1/2 parts well-graded white or light-colored sand with sufficient water to make a creamy mixture may be placed over the aggregate. If a mortar facing mix is used, the backup mix should be of a low slump with a maximum of 1 in. (25 mm) to absorb excess water from the facing mix; otherwise, the backup mix should be a standard structural concrete with a slump of 2 to 4 in. (50 to 100 mm). The mortar mix or part of the backup concrete should be carefully shoveled onto the stones and further spread and lightly tamped with trowels to ensure that it is worked around all the individual stones, then it should be screeded to a flat surface before the steel is placed. Care should be taken not to dislodge any of the face stones when placing the first layer of mortar or concrete. Also, care should be exercised during vibration so as not to disturb the sand or large stones, which could cause uneven stone

distribution. Upon stripping the precast concrete units, they should be raised, and any clinging sand should be removed by brushing, air blasting, or high-pressure water washing. Some sand bonds to the concrete; therefore, the color of the bedding sand should be carefully chosen to harmonize with the exposed stones.

30.6.3.2 Veneer Facing Materials

When natural stone veneer is used, it is recommended that the purchaser of the stone engage someone qualified to be responsible for coordination, which includes delivery, scheduling, and ensuring color uniformity. In evaluating properties of stone, it should be recognized that some natural stones exhibit different properties in different orientations. Also, there may be considerable variation in a given direction of grain for different samples of the same stone. The thin sections of stone are generally more sensitive than thicker sections to strength decreases due to imperfections and inclusions of minerals. Also, a stone that has a crystalline structure with dimensions large enough to approach the thickness of the slab itself will be substantially weakened. In addition, the surface finish, freezing and thawing, and large temperature fluctuations will affect the strength and in turn influence the anchorage system. Non-acid-based masking or plastic tape may be used to keep concrete out of the stone joints so as to avoid limiting stone movement (PCI, 1996).

Color control or blending for uniformity should be done in the stone fabricator's plant because ranges of color and shade, finishes, and markings such as veining, seams, and intrusions are easily seen during the finishing stages. A qualified representative of the owner, who understands the aesthetic appearance requested, or the owner or architect should perform this color control. Acceptable color should be judged for an entire building elevation rather than for individual panels. All testing to determine the physical properties of the stone veneer should be conducted by the owner prior to the award of the contract. This will reduce the need for potentially costly repairs or replacement should deficiencies in the stone veneer be found after start of fabrication. When purchasing the stone, the contractor should be sure to order an additional 5% to cover breakage and incorrect sizing by the supplier.

A complete bond breaker between the natural stone veneer and concrete should be used. Connecting the veneer to the concrete should be done with mechanical anchors that can accommodate some relative movement. When using epoxy in anchor holes, 1/2-in.-long compressible rubber or elastomeric grommets or sleeves should be used on the anchor at the back surface of the stone. Thin brick (1/2 to 1 in. thick) rather than whole bricks are generally used in precasting because adequately grouting the thin joints with whole bricks is difficult and results in the use of mechanical anchors. Some bricks are too dimensionally inaccurate for precast concrete applications. They may conform to an ASTM specification for site laid-up application, but they are not manufactured accurately enough to permit their use in the preformed grids that are used to position brick for a precast concrete unit. When both site-laid brick and brick precast units are to be used on the same project, the contractor has to be sure the precast tolerance requirements govern. Because variations in brick or tile color will occur, the clay product supplier should preblend any color variations and provide units that fall within the color range selected by the architect. Ceramic glaze units, where required for exterior use, may craze from freeze-thaw cycles or the bond may fail on exposure; therefore, the manufacturer should be consulted for suitable materials and test data.

30.6.3.3 Honed or Polished Surface

Grinding concrete produces smooth, exposed-aggregate surfaces. The grinding is called *honing* or *polishing*, depending on the degree of smoothness of the finish. Polished exposed-aggregate concrete finishes compare favorably with polished natural stone facades, allowing the architect great freedom of design. Honed and polished finishes have gained acceptance because of their appearance and excellent weathering characteristics, which makes them ideal for high traffic areas and polluted environments. To produce a good ground or polished finish, it is first necessary to produce a good plain finish. The compressive strength of the concrete should be 5000 psi before the start of any honing or polishing operations. All patches and the fill material on any bug or blow holes or other surface blemishes must also be allowed

to reach approximately 5000 psi. It is preferable that the mortar strength of the concrete mix approach the compressive strength of the aggregates, or the surface may not grind evenly or polish smoothly and aggregate particles may be dislodged. Because aggregates will polish better than the matrix, it is essential to have a minimal matrix area. A continuous graded concrete mix heavy in coarse aggregate is preferred, one that is carefully designed to provide maximum aggregate density on the surface to be polished. In choosing aggregates, special attention should be given to maximum size and hardness. Softer aggregates such as marble or onyx are much easier to grind than either granite or quartz. This will be strongly reflected in the cost of such finishes.

30.6.4 Combination Textures

The combination of a polished or honed surface and acid etching provides a surface on the precast unit that exposes a very high percentage of stone. After the grinding process, the acid removes the cement matrix and fines between the larger aggregate particles. This surface is highly resistant to weathering and is self-cleaning to a high degree. The color of the aggregates predominates in the combined polished acid-etch surface texture. A polished/sandblast finish on a precast unit provides contrast between the smooth polished aggregate and the sandblasted matrix of the concrete. The architect must ensure that the overall design concept includes suitable demarcation between the two textures, as sandblasting overflow will dull the polished surface. In many cases, stone veneer is used as an accent or feature strip on either precast units or cast-in-place concrete. When a stone veneer is applied in combination with other finishes, a 1/2-in. (12-mm) space is left between the edge of the stone and the adjacent concrete to allow for differential movements of the materials. This space is then caulked as if it were a conventional joint.

Combination finishes involving the use of one or more basic finishes together with form liners are almost infinite. Liners can be used in combination with smooth sandblast, acid, retarded, or tooled textures for either cast-in-place or precast concrete. Care in developing details must be taken to include suitable demarcation between the different textures. Some of the usual combinations include:

- Heavy abrasive blast/light abrasive blast/smooth
- Striated/abrasive blast/irregular pattern form liner
- Acid etch/abrasive blast/smooth
- Ribs or vertical rustication/acid or abrasive blast
- Tooled/hammered/form liner
- Tooled/hammered/abrasive blast
- Tooled/chiseled/smooth

30.7 Construction: Cast-in-Place Concrete

30.7.1 Forming

30.7.1.1 General

The selection of forms and forming materials to accomplish a given task is usually limited by the parameters established by the architect in the drawings, specifications, and samples and by the contractor's mock-up. Specified forms and surface treatments become vitally important to a successful project when used for architectural purposes. Any material that can contain plastic concrete without deformation is a potential concrete form. Forms must withstand the loads due to both liquid head and compactive effort. This means that the forms must support a full liquid head. With the use of concrete pumps, the concrete can be placed rapidly with a minimum of lift lines. If the forms are not able to fully support the liquid head, bottom movement will occur, resulting in concrete spillage or actual movement of the upper form from the plane of the form below (Figure 30.12). Lightweight form systems are designed for concrete placement at 6 to 8 ft (1.8 to 2.5 m) per hour. This may be insufficient. The most common forms are made of wood, plywood, concrete, steel, plastic-reinforced and nonreinforced, plaster, or a combination

FIGURE 30.12 Movement of upper form from the plane of the form below during placement and consolidation of the concrete.

FIGURE 30.13 Moisture leakage at nail holes and at the edges of duct tape used at form butt joints reduce the w/c ratio at the point of migration, resulting in dark areas in the concrete surface.

of these materials. For complicated details, forms of plaster, elastomeric rubber, foam plastic, or sculptured sand may be used. These forms are often combined or reinforced with wood or steel depending on the size and complexity of the unit to be produced.

Forms are molds, and the cast concrete surfaces will reflect the finest details of the contact surface: wood grain, nail heads, dents, bulges, and the tile smootheners of plastic. All of these can be reproduced with startling—and sometimes distressing—fidelity. This should be remembered when choosing the forming material. Moisture leakage at nail holes and at the edges of the duct tape used at form butt joints reduce the w/c ratio at the point of migration, resulting in dark areas in the concrete surface (Figure 30.13). Overuse of forms can result in wear in areas with variable absorption. Forms that are to be reused should be carefully inspected after each use to ensure that they have not become distorted or damaged and to determine if they have any surface deterioration that may affect their ability to perform. Dark blemishes of this nature may penetrate as much as 1 in. (25 mm) into the concrete (Figure 30.14 and

FIGURE 30.14 Poor-quality form surface where the dense plywood and its surface coating have been worn through repetitive usage.

FIGURE 30.15 Result of form with vertical wear marks reflected in the finished concrete surface. Sandblasting made the surface blemishes more apparent.

Figure 30.15). Once they occur, they cannot be concealed by sandblasting or bushhammering. In fact, due to its low w/c ratio, this dark concrete is actually harder than the adjoining unaffected areas and there will be less erosion from sandblasting, which will tend to accentuate the blemishes. Regardless of the number of reuses, all forms should produce concrete surfaces matching the approved mock-up.

30.7.1.2 Materials

The selection of form materials is the responsibility of the contractor, although the architect may specify certain liners or materials to achieve a particular surface or texture. Selection of materials used for forming must consider the type of surface effect desired, which includes color impact, texture, quality, deflection, and ease of stripping. Economy is of major concern to the contractor and is a function of cost first and then the number of possible reuses while still meeting the criteria of the mock-up.

Deflection, rather than bending or horizontal shear stresses, generally governs the design of the formwork. Forms must be able to support their own weight, the weight of the plastic concrete, and the pressure of the forces from consolidating the concrete. Deflections in the contact surfaces of the formwork

reflect directly in the finished concrete surfaces. Forms for architectural concrete must be designed to minimize deflection. The deflection factor as well as the layout of tie-cone holes will affect the number of studs and wales or the number of studs and size of wales in the case of wooden forms. Limiting deflections may be only 1/16 in. (1.5 mm) in 4 ft (1.2 m), which is only half the normally acceptable 1/360 of the span for structural concrete. This limiting deflection is the one that is most restrictive yet still practical. Generally, prefabricated wooden form panels are not suitable for use in architectural concrete due to difficulties encountered in making them tight against leakage; therefore, wooden forms for walls are generally built in place. Particular care must be given to alignment, perfection of corners, quality of contact surface, and tightness of joints. Minor defects in any of these items, which may not be objectionable in structural concrete, are not acceptable for architectural concrete.

In any architectural project, the formwork must be superior to that used for structural concrete. Grade B-B plywood is often used for structural concrete construction but generally is not acceptable for architectural concrete. This plywood absorbs moisture from the concrete and will cause discoloration unless two to three coats of a urethane sealer are applied prior to use. High-density plywood can be used 10 times or more. Today, plywood can be purchased with plant-applied surface treatments that provide a nearly impervious and smooth surface. Birch plywood with a plastic coating is a plant-produced product that is higher in cost, but its high rate of reuse and its availability in sizes larger than 4×10 ft (1.2×3.1 m) may offset the cost by reducing the number of butt joints. If grain raise is to be transferred to the concrete, impervious coatings should be avoided. Sandblasting the plywood surface will impart a rough grain texture to the concrete.

Steel forms are generally used where high reuse factors or full liquid head construction is required. Steel surfaces are impervious and can provide uniform color to the concrete. The concrete may have some texture or color variation if the steel is rolled in different mills. An epoxy coating on the steel faces can combat the possibility of rust. The steel skin should be thick enough to support the load between its support members and keep deflections within acceptable limits. Quality steel forms should be well braced and manufactured of a heavy enough gauge steel to prevent twisting, buckling, and bending during erection and under the most severe usage. Formwork should incorporate adequate ribbing or channeling to provide rigidity, and, when welded to the parent member, the welded areas must exceed 6 in. (150 mm) in length to prevent tearing or popping. Skip-welding should be used instead of continuous welding to keep heat out of the plates. If continuous welding must be done on a finish surface, it is recommended that a test section be produced at the joint to determine whether or not the joint area produces an acceptable product without distortion in the concrete. The welds should be ground smooth and coated with epoxy or similar material to hide the joint. Steel plate should come from the same mill as the steel may be rolled in a variety of ways. Variations in the rolling technique can cause differences in the appearance of the concrete cast against metal from two mills. The steel skin should be pickled to remove mill scale. Bluing over welded material has been beneficial for avoiding staining from different surface characteristics. For flat horizontal surfaces and surfaces to be honed or polished, the form skin should be 3/8 in. (10 mm) thick to maintain local flatness after repeated use. Higher plate inertia also imparts a more uniform vibration pattern across the concrete surface during form vibration.

Steel is the preferred forming material for external vibration because it has good structural strength and fatigue properties. Steel forms are well suited for the attachment of vibrators and, when properly reinforced, provide good uniform transmission of vibration. Welding at the corners of vibrator-mounted members or brackets should be avoided, as this promotes angular crack propagation. Galvanized steel forms may cause concrete to stick and should be avoided. Aluminum and magnesium alloys may be used successfully if they are compatible with concrete. There is no standard test to measure compatibility. Past history of use with the same concrete mixture, forms, and curing conditions is the best known indicator of compatibility.

Fiberglass-reinforced plastic is an excellent solution when it is possible to use one form face piece for two or more adjacent surfaces. Examples are a beam face and soffit or the front and two sides of a column. In this way, the support members required in a fiberglass-reinforced form can be integral with the finish face. Such forms can ensure that there will be no leakage at the completely enclosed corners, thus minimizing one of the most objectionable surface blemishes (leakage) in architectural concrete

construction. Designers may not like the slightly rounded corners, but no one prefers leakage lines. Fiberglass-reinforced forms must have adequate horizontal and vertical ribs to properly provide rigidity and resistance to deflection.

An appropriate resin must be used on the surface face to ensure good performance through a reasonable number of reuses, usually over 100. Maintenance of the resin plastic is mandatory for surface uniformity. This can be accomplished by careful cleaning, use of release agents, and occasional touch-up of the face surface. Surface conditions, joints, and gel-coat material should be visually inspected prior to each use. Plastic molds should not be used with accelerated curing if concrete temperatures above 140°F (60°C) are anticipated. The susceptibility of the plastic form to attack by the proposed release agent should be determined prior to use. Unreinforced plastics are normally used only as liners for a form system designed to meet all of the structural requirements of concrete containment. Unreinforced plastic is only used to change the characteristics of the surface.

Plaster waste forms are used for custom designs of a sophisticated and detailed nature. The concrete is cast against the mold and the plaster is then broken away from the finished surface. Loose plaster can be removed with high-pressure water washing. Forms are almost always made with ornamental plasters, the methods used being similar to those employed in fibrous plaster work. Plaster forms must be made in sections that can be handled easily; individual pieces should not weigh over 150 lb (68.2 kg). Plaster forms are usually given two coats of white shellac to make them waterproof and nonabsorbent. If this is not done, it is quite certain that there will be a difference in the color of the concrete as compared with adjacent areas. Obviously, one-use forms are relatively expensive and should only be used for nonrepetitive forming or where intricate shapes cannot be formed by more conventional methods. An effective release agent must be used with plaster waste molds.

30.7.1.3 Joints

A surface blemish will result when water is allowed to leak from the form. Leaks of any type in forms will result in honeycomb (an aggregate-rich surface inconsistent with the normal, dense, adjacent surfaces accompanied by a color change or streaking), mottling, or a dark discoloration surrounding the point of leakage. The darker surface color is a result of less water being available for hydration. Moisture, paste, or grout can never be replaced except by repair of the concrete surface. It is therefore very important to prevent leakage. Different methods have been advanced to prevent leakage at form joints; none has proved completely successful, especially those attempting to seal the joints flush with one another. Any amount of moisture or grout will create blemishes in exposed surfaces that are difficult and that may even be impossible to remove. For this reason, many designers prefer to acknowledge the joints and mask them with reveals formed by rustication strips. It is good practice to provide rustications at the casting limit atop the preceding cast to define straight level and plumb working lines (Figure 30.16) for construction joints (Shilstone, 1973a).

When concrete is placed for the lift above or for an adjoining wall section, the forms will have a tendency to bulge under the hydrostatic head of the wet concrete and vibratory loads, causing a spill or overpour on the concrete already in place (Figure 30.17). Unless the concrete is to be bushhammered, tooled, or heavily sandblasted, which in the process remove the spill, such an overpour should be prevented. This is best accomplished by attaching a compressible gasket that is set into the reveal at the top of the previous casting and provides a watertight seal beneath the reveal. Tying the form into the previous concrete placement after the gasket is in place helps prevent form deflection. Vertical joints can be handled in a similar manner (Shilstone, 1973a).

Control joints may be defined as planes of weakness created by thin sections, encouraging the concrete to crack at predetermined locations. Stresses that cause cracking result from shrinkage, thermal effects, and differential settlement; shrinkage is generally the stress of greatest magnitude. If joints cannot be tolerated, the reinforcement design can attempt to distribute shrinkage and thermal stresses into many small hairline cracks, but it is generally better to weaken the concrete and ensure a controlled crack that can be sealed against water penetration. At times, it is desirable to cut 50% of the temperature steel at the control joint to further weaken the section.

FIGURE 30.16 Typical construction joint; horizontal or vertical—no scale. (From Shilstone, J.M., *Architect. Rec.*, 161–164, 1973. With permission.)

The location of control joints should not be determined until a careful study has been made of the geometry of the structure, its elastic qualities, and the steel-reinforcement design. It is an inescapable fact that a large mass of concrete will crack. This must be anticipated in the structural and architectural design. Perhaps the surest way to plan construction joints, and one that reduces their number, is to have them correspond to locations where control joints are required. The relatively weak bond between castings will ensure that cracks develop at those points.

On many occasions, chamfers have been used at corners in an attempt to minimize leakage. If the chamfers themselves are not caulked or gasketed, moisture or paste leakage can occur at two points rather than one. It is recommended that all corners, form joints, horizontal and vertical construction joints (sometimes known as cold or pour joints), and control joints be caulked or gasketed to provide positive protection against leakage. Gaskets should be a closed-cell compressible neoprene with adhesive on one side that can be attached to the form. Plastic pressure-sensitive tape (never duct tape) has sometimes been used on the inside of the forms at butt joints when significant texturing of the surface skin is planned. To withstand the stress when the form is filled with concrete, the tape should be flexible and highly adhesive. Tape should be applied prior to the application of a release agent. Care must be taken to prevent displacement of the tape or gaskets during concrete placement. Brush-applied gum adhesive over tape has been used successfully to stabilize the tape or gasket against movement. All joints should

FIGURE 30.17 Spill or overpour at construction joint during placement and consolidation. Tying the form into the previous concrete placement and installing a compressible gasket in the reveal would have prevented this leakage.

be inspected prior to casting to be sure the tape or gaskets have not moved. When tape cannot be used because tape deformation will be visible on the fine texture concrete surface, great care must be given to locating the butt joints. It is recommended that the contractor erect the exposed form face first to allow a visual check of all joints and joint treatments to minimize potential leakage.

Other ways to seal plywood butt joints include chamfering form edges and filling them with epoxy, gasketing, and using plywood sheets that have spliced or tongue-and-groove edges that are caulked or glued. Such joints must be backed up and supported with 2×4 s (50×100 mm). The architect may designate the location of control joints, but the location of construction joints is often left to the contractor. In architectural concrete, it is best if the contractor receives input from the architect as to where construction joints will be located.

30.7.1.4 Form Ties

Except for small columns and beams, the lateral forces created by the hydraulic pressure of plastic concrete must be resisted by horizontal ties that hold the forms together and maintain their position. Ties may incorporate a spreader device that correctly spaces the distance between forms and acts as a means of removing metal parts to a sufficient depth from the surface, 1-1/2 in. (38 mm), to facilitate patching with mortar and prevent corrosion. Form ties significantly influence the visual effect of architectural concrete. They are placed in the forms in a pattern that should be consistent with the type of form design (Shilstone, 1973b). A 4-ft (1.2-m) pattern can be used with a variety of plywood sizes in a gang form. There is a tendency for many contractors to use cone snap ties. The installation of these must be done very carefully. All form-tie systems should incorporate a positive leakage-prevention detail. Bulls-eyes around tie holes are not considered attractive. Leakage can occur around form ties if they are not perfectly seated and sealed (Figure 30.18).

FIGURE 30.18 Dark leakage areas around form tie holes where moisture has migrated, resulting in localized concrete with a lower w/c ratio.

Tie-hole design and spacing are as much architectural considerations as a structural requirement for the contractor. Ties for architectural concrete should be planned so they are symmetrical with the member formed, and, wherever possible, ties should be located at rustication marks, control joints construction joints, or other points where the visual effect will be minimized. In this way, repair of tie holes will not fall in the flat panel areas. Successfully patching tie holes is not easy because it is difficult to match the finished color of the adjacent concrete surfaces. Often, patches tend to accent rather than conceal tie holes. Heavier forms with steel backing and large-diameter tapered bolts at a minimum number of locations offer a better approach to architectural concrete than using multiple snap ties. Adjustable, high-strength bolt ties facilitate the installation of subsequent forms by holding them tightly to the concrete of the previous casting, helping prevent leakage.

Ties or bolts that are to be pulled from the form must be coated with nonstaining bond breaker or encased in oiled paper sleeves to facilitate removal. Ties for architectural concrete should have the same safety factor as structural concrete. Form-tie assemblies for architectural concrete should be adjustable so as to permit tightening of the forms. Form-tie assemblies fall into one of the following groups:

- Continuous, single-member ties for specific wall thicknesses and positive breakback characteristics
- She-bolt ties, where an inner male threaded unit is left in the wall concrete and the outer fastening devices are removed and reused
- He-bolt ties, where the outer fastening devices are reused and an expendable female threaded unit is left in the wall
- Through-bolts placed through PVC pipe with removable plastic cones at the ends
- Tapered high-strength through-bolts, which can be completely removed from the concrete

The last type of bolt has a separate outer unit for proper adjustment. When using these bolts, the contractor should place the small-diameter side of the tapered bolt on the exposed face to avoid spalling when the form is stripped. Removable ties should be of a design that does not leave holes in the concrete greater than 7/8 in. (22 mm). Bolts should be tight fitting or holes should be filled with a sealant to prevent leakage at the holes in the form. All of these ties leave round and relatively clean holes, providing proper sealing procedures have been used (ACI Committee 303, 2004). These holes may be left alone, patched flush, or patched with a slight recess for an architectural shadow effect. Snap ties are not suitable for architectural concrete unless a rustic crude look is desired.

30.7.1.5 Form-Tie Removal

Ties should be removed as soon as possible after the formwork has been removed. After forms are removed, uncoated ties or ties that possess staining tendencies should be snapped and the ends should be treated to prevent rust stains. Stainless-steel snap ties, when used, present the least trouble with staining, but still should be broken off at least 1 in. (25 mm) behind the finished surface. Plastic-coated ties should be snapped and the ends treated to prevent rust staining. Holding forms together with twisted wire ties or band iron should not be allowed, as it is nearly impossible to obtain a long-term, stain-free surface without cutting into the concrete surface and cutting back the tie or band iron ends before repairing a rather large nonuniform area. Externally braced forms may be used instead of any of the above-mentioned form-tie methods to avoid objectionable blemishes in the finished surface. This is an expensive alternative unless a high degree of repetitive form use is possible.

30.7.1.6 Form Removal

Assuming that the necessary planning, care, and workmanship have been exercised in producing the quality of work desired, form removal must maintain the results already achieved. Forms should not be removed until the concrete has sufficiently hardened to permit form removal without damaging the concrete surface. Prying against the face of the concrete should not be attempted. When necessary, wooden wedges (not metal), should be used to assist in form removal. Many surfaces are marred by the use of metal wedges to loosen forming. Rough removal of forms may damage them beyond reuse. Elastomeric liners become difficult to remove if the forms are not stripped within 5 to 7 days. Easy removal of forms will reduce labor costs. More importantly, forms that can be stripped easily prevent unnecessary damage to exposed architectural surfaces. Spalled edges require expensive restoration by knowledgeable craftsmen. Sharp corners require a considerable amount of special attention in forming and form removal technique. Sharp edge lines and corners are very vulnerable to chipping or spalls at early ages. Damaged corners require costly repair work.

If forms are removed before the specified curing period is completed, measures must be taken immediately to apply and maintain satisfactory curing. In hot, dry climates, wood forms remaining in place should not be considered to be adequate curing. Forms should be removed or loosened so the concrete surfaces can be kept moist, or they should be coated with a curing agent. In cold weather, architectural concrete should not be allowed to cool more than 40°F (4.4°C) per 24 hours following the cessation of heat application. The removal of formwork may have to be deferred, or formwork that is removed should be replaced with insulated blankets to avoid thermal shock and consequent crazing of the concrete surface.

One has to be careful of small projections such as drip lines. Abrupt stripping may crack or break off the projecting tip, making the area vulnerable to moisture and subsequent corrosion of reinforcement. With embedded items such as windows or forms for openings, braces should be stripped first to allow the edge forms to be stripped without spalling the concrete. Intricate details will require a delay in stripping time to allow the concrete to gain sufficient strength and to shrink from drying (Dobrowolski, 1989). The best procedure calls for stripping to begin away from the intricate area and proceed toward it. If the edges of rustications are to be crisp after sandblasting, they must remain in the face of the concrete. Many reuses call for rustication strips to remain with the forms and new strips to be reinserted prior to sandblasting. Fastening can be by gluing with mucilage or nailing into the form.

Once formwork is removed, the concrete must be protected to prevent damage from any means including subsequent construction operations and weather. Runoff water from rain or on-site construction should be prevented from running over iron or other materials that can cause staining and then running over finished faces of architectural concrete. Surfaces must be protected from stains, graffiti, and impact damage. Differentiating concrete color hues may be expected between two surfaces where adjacent formwork is stripped at different ages. It is best to strip all adjacent form surfaces at about the same age for greatest uniformity. All forms, regardless of material selected, must be stacked level and horizontal to prevent warping. Even steel forms will warp if stored at an angle against the side of a building.

FIGURE 30.19 Electrical conduit blocking access for placement and consolidation of concrete.

30.7.2 Reinforcement

30.7.2.1 Reinforcing Steel

Reinforcing steel must be planned in advance so concrete placement can be carried out without reinforcement, thus reducing the work space required for consolidation of the concrete. Mechanical, electrical, ductwork, piping, conduit, or other embedments must also be planned as to location (Figure 30.19). If the size of a particular member does not provide adequate work space or otherwise presents difficulties for the contractor, an alternative method of detailing or construction should be considered. Often the suggested solution for a congested member is to use a smaller vibrator. This can be a problem, as the smaller vibrator may not be able to perform the compactive work necessary to produce the high quality essential for architectural concrete.

Occasionally, special vibrators have been made, such as vibrators with rigid shafts and only a 3-in. (76.0-mm) flexible joint. Even special vibrators cannot overcome lack of space. Because the amount of reinforcing required in a member is dependent on the size of the member, it may be necessary to increase the size of the member. Members cannot always be slim enough to meet the architect's design concept. Concrete members must be of sufficient size to avoid excessive amounts of reinforcing steel. Visualizing the patterns of reinforcing is important at the early stages of design—particularly at member intersections (Figure 30.20). The situation in Figure 30.20 allows little room for placement and consolidation of concrete. Honeycomb and other surface blemishes are a certainty; for example, beams should be wider than columns that have to go through the floor to avoid the familiar solid maze of vertical and horizontal

FIGURE 30.20 Intersection of reinforcing steel allowing little access for placement and consolidation of concrete.

FIGURE 30.21 Bundling of reinforcing bars to allow more working space for vibration.

reinforcing. In other members, bundling bars may provide a solution to afford clear working space for vibration (Figure 30.21).

The assumption that reinforcing steel must be uniformly distributed as detailed on the structural drawings is not always accurate. In many designs, the steel bars can be bundled or otherwise spaced to allow the contractor some space to actually place and consolidate the concrete. Horizontal space available after bundling will allow entry of the vibrating equipment. Full tension welds, cadwelds, or tension splices can be employed where required to eliminate congestion caused by lapping of bars (Figure 30.22). Locating the lapping of bars throughout the beam can reduce the congestion at any one point.

Reinforcing steel for architectural concrete must be accurately positioned and held in place in such a way as to minimize movement during placement and consolidation of the concrete. Wall or beam reinforcement cover can be maintained by the use of bolsters or chairs on the inside face of the form to lessen the chance of rust stains or spalling of the concrete. When reviewing the reinforcing steel design, the contractor should consider the following:

FIGURE 30.22 Lapping of bars all occurring at one location causing congestion that can lead to honeycombing.

- For design purposes, the cover on reinforcing steel for concrete exposed to the weather should be at least 2 in. Because the ACI Code allows reinforcing metal to move $\pm 1/2$ in. from the design location, this sets a minimum of 1-1/2 in. of cover over the reinforcement.
- Horizontal bars in walls should be placed toward the outside face of the wall to allow a larger casting space between curtains of reinforcement (Figure 30.23). Single-curtain reinforcement should be positioned at the center of the wall, but with the horizontal bars closest to the architectural face.
- A minimum clear working space of 5 in. (design) is necessary to facilitate proper placement and consolidation of low-slump concrete mixes.
- When computing the space occupied by the reinforcing steel to determine the amount of space available for the worker in the field to do the work, maximum bar diameters should be used instead of the nominal diameters. The effective space occupied by the bars due to deformations is over 10% larger. Actual space is measured to the outside of the deformations on the rebar surface. These maximum deformations become significant when thin or slender concrete sections are to be cast.
- Tie wires should be a soft stainless steel specified to be tucked behind the joints and not left dangling adjacent to the exposed face.
- Chairs should not be used to space reinforcing steel from vertical surfaces. Where it is necessary to support steel in beams, the reinforcing steel should be hung from the forms with stainless steel tie wire, and any chairs should be plastic tipped with sufficient plastic cover to ensure that the metal will not rust. If reinforcing steel is hung from the forms, the forms and supporting member must be designed to take what is often very heavy weight. This method is generally only practical when steel forms are used. If the surface is to be abrasive blasted, consideration should be given to the material that will resist the abrasive blast. In most cases where there is heavy reinforcement of beams, it may be necessary to use precast concrete blocks of the same concrete used in the construction to support the metal.

Some design codes require the use of reinforcement in such quantities that constructability is markedly reduced. When such conditions are found, the fact that the amount of metal required is within the code is not an acceptable excuse for producing a design that defies proper construction. Double-check reinforcing steel details to make sure that casting space is available. For the project manager, this can be the difference between a reasonable project or an impossible task.

FIGURE 30.23 Double steel curtain wall: may be finished both sides; 12 in. usually minimum (not to scale).

30.7.2.2 Placing Accessories

Supporting chairs, spacers, and bolsters should be manufactured of plastic or stainless steel to prevent surface rust staining, particularly where the concrete member is to be sandblasted. Plastic colors should match the finish surface. Many steel accessory suppliers will custom color their products. Current practices in detailing are considered inadequate to achieve total concealment of accessory feet. The reinforcing steel specification should indicate the need to increase the number of chairs to compensate for steel loads that cannot be tolerated by the plastic-covered chairs, the plastic tips of the chairs, or the form materials used to support the reinforcing cages. Insufficient chairs may cause form indentation. Upon removal of the forms, these plastic or stainless steel tips will project below the ceiling or from the bottom of cast-in-place beams. Any plastic coating tips should be investigated for durability if they will be exposed to weather or sunlight. Any wire for tying reinforcement should be of soft stainless steel to minimize staining of exposed surfaces. Some stainless steel ties may rust slightly when sandblasted or exposed to severe weather conditions. For this reason, all tie wire should be cut as close as possible to the bars and bent back away from form surfaces. Tie-wire clippings must be removed from any horizontal surfaces (such as beam soffits or ceiling areas) that will be exposed to view.

30.7.2.3 Galvanized Reinforcement

Galvanizing reinforcing steel is not recommended for architectural concrete. Adequate minimum cover of well-compacted concrete is the best protection for reinforcing steel. Where galvanizing of reinforcing bars is required, galvanizing is usually performed after fabrication. This may mean several rehandlings

FIGURE 30.24 Plan view of typical interior shearwall anchorage. Pocket formers can be field adjusted for proper tendon alignment.

for individual bars or partially assembled cages. ASTM A 767/A 767M (ASTM, 2005) prescribes minimum finished bend diameters for bars that are fabricated before galvanizing. Smaller finished bend diameters are permitted if the bars are stress relieved. Supplementary requirement S1 requires sheared ends of bars to be coated with a zinc-rich paint formulation. When galvanized reinforcing steel is placed close to nongalvanized metal forms, the concrete may have a tendency to stick to the forms. This may also happen if nongalvanized reinforcement is used close to galvanized forms or form liners. A 2% solution of sodium dichromate or a 5% solution of chromic acid (chromium trioxide) solution applied as a wash to the galvanized surface has satisfactorily reduced the galvanic action of the metal to prevent reaction between the zinc and the alkaline fresh concrete. The addition of chromates to the concrete cannot be recommended, as their effect on concrete performance is not yet fully known. Galvanizing of reinforcement is only recommended when minimum cover requirements cannot be achieved. In these cases, the use of galvanizing should be specifically called for in the contract documents and shown in the shop drawings.

30.7.2.4 Post-Tensioning

Long-span, post-tensioned-beam framing systems have been used in combination with architectural concrete to produce unusual buildings in both the United States and the Middle East. A post-tensioned-beam framing system offers the advantages of both a higher span/depth ratio and a reduction in material quantities. With an architectural cast-in-place facade, considerable planning is required to allow for stressing of the post-tensioned structure without leaving visible signs in the exterior architectural finish. This means using exterior precast concrete panels as covers for exterior stressing pockets or providing interior stressing pockets, buttresses, and blockouts.

The contractor must be very careful in his placement of anchor pocket formers in the formwork. Improper placement of formed stressing pockets can result in misalignment of jacking equipment and application of an incidental biaxial force to the tendon, which could cause shearing of the tendon at the anchor. Preformed pocket formers can be used and field adjusted to obtain the proper alignment of typical interior shearwall anchorage, as shown in Figure 30.24. An interior girder detail at the core stressing anchorage and at the exterior wall key are shown in Figure 30.25. The 60-ft (18.3-m) single-span beams in the low-rise structure are stressed through to pockets at each end of the beam. A typical top pocket anchor detail is shown in Figure 30.26. The above three details were used at 1515 Poydras in New Orleans. Chicago-based Skidmore, Owings, and Merrill provided the architectural and engineering

FIGURE 30.25 Interior girder detail at core stressing anchorage and at exterior wall key.

FIGURE 30.26 Typical top pocket anchor detail.

design. The unusual number of unique post-tensioned-beam anchorage configurations required intense review and quality control at the onset of construction. Considerable planning went into materials, formwork sequencing, and special falsework for the doweled reinforcement support. This is a striking example of the integration of structure and form. The exterior concrete finishes range from a heavy hammered texture to a light sandblast. Attention to detailing, finishes, and execution have allowed the architectural design of this building to be accurately expressed through cast-in-place and precast structural elements (Clark and Zils, 1984).

The original design of the post-tensioned channel beams at the roof level of the 800-ft (244-m)-long Physical Education building in Saudi Arabia called for massive 4.0-ft (1.2-m)-wide by 8.0-ft (2.4-m)-deep by 141.6-ft (42.9-m)-long cast-in-place concrete beams spanning 120 ft (36.3 m) between cast-in-place lateral supports. Each beam would have a total mass of 170 t (154 Mg) and an architectural surface area of 4670 ft² (432 m²). These channel beams were located 56 ft (17 m) above ground level and spaced

FIGURE 30.27 After all seven-wire strands were stressed and anchored, the ends were cut off inside the stressing pocket recess.

16.3 ft (4.95 m) on-center. The 47 beams were of architectural concrete with a light to medium sandblast finish. Due to severe schedule restrictions, shoring problems, and interference with work at other levels and zones of the building, it was decided to precast and post-tension the channel beams rather than cast them in place. The precasting would take place at one location at the 56-ft (17-m) level. Caudill Rowlett & Scott (CRS) in Houston, Texas, approved the design modification. This change in construction method reduced shoring and forming costs and resulted in a large reduction in labor. The channel beams were cast on a construction platform on a 6-day cycle, including 3 days of curing on top of temporary rails set on the cast-in-place lateral support beams. Seven-wire strand was threaded through sheathing to ensure minimum friction losses. After 6 days, the strands were tensioned following a computer program that determined the required gauge pressure and elongation for each strand group. When all of the strands had been properly stressed and anchored, the ends were cut inside the stressing pocket recess (Figure 30.27). Strands were then grouted in the sheathing, and the recess was filled with architectural concrete patch mix, covered with wet burlap, and protected with a wood cover (Figure 30.28). Each channel beam was moved to its final position along the rail using two hydraulic rams. After the beams reached their final position, the hydraulic ram jacking system and rails were removed and the beams were set on thick neoprene bearing pads. This was all done without the use of a crane; only hydraulic jacks were used (Kenney, 1988).

A prestressing strand is required to conform to ASTM A 416 (ASTM, 2006), Grade 250 (1725) or Grade 270 (1860). The most commonly used grade of steel is 270,000 psi (1862 MPa). This strand is 0.5 or 0.6 in. (12.7 or 15.2 mm) in diameter and is of low-relaxation type. Unbonded single-strand tendons

FIGURE 30.28 After cutting, the strands were grouted in the sheathing, and the recess was filled with architectural concrete patch mix, covered with wet burlap, and protected with a wood cover.

are composed of steel strand with anchors affixed to each end by toothed wedges coated with corrosion-resistant lubricant and encased in plastic sheathing. For wedge-type anchorages, the wedge grippers should be designed to preclude premature failure of the prestressing steel due to notch or pinching effects under static test load conditions.

Post-tensioning tendons subject to exposure or condensation and that are not to be grouted should be permanently protected against corrosion by plastic sheathing formed over the coated (greased) strand or by other appropriate means of protection. The sheathing should not be reactive with the concrete, coating, or steel. The material should be watertight and have sufficient strength and durability to resist damage and deterioration during fabrication, transport, storage, installation, concreting, and tensioning. Sheaths should be continuous over the unbonded length of the tendons and should prevent the intrusion of water or cement paste and escape of the coating material.

30.7.3 Concrete Placement

The placement of architectural concrete requires the utmost care on the part of the contractor. Consistent preplanning of each day's concrete placement should be done. The period between the truck and the forms is the most critical time in the life of architectural concrete. The ready-mix truck must transport and mix the concrete to a homogeneous state in spite of low slumps and high coarse-aggregate contents. With some architectural concrete mixes, it may be necessary to load trucks to only two thirds of their rated mixing volume. The contractor must verify that the ready-mix trucks assigned to deliver architectural concrete are clean and free of hardened buildup and have less than 20% blade wear. Trucks meeting this criteria should have their numbers recorded, or some other means of identification should be used so only approved trucks will be used for architectural concrete. Trucks should be scheduled so they arrive at the project site just before the concrete is required, thus avoiding excessive mixing while trucks are waiting or delays in placing successive lifts of concrete. Delays cause nonuniformity of pour line or appearance.

A major decision for the contractor is choosing the method for placing the concrete. Placement can make or break the quality of architectural concrete. The characteristics of certain lay-down buckets or pumps may prevent their use for placing the necessary concrete mix. When this happens, other methods or equipment may be required. Steep-sided buckets (Figure 30.29), may be required, conveyors may be used (Figure 30.30), or a different concrete pump may be selected (Figure 30.31). Change the equipment or pump, but do not adjust the concrete mix design.

FIGURE 30.29 Steep-sided bucket with easily movable chute to aid in placement of concrete.

FIGURE 30.30 Conveyors in use at construction site.

FIGURE 30.31 Several concrete pumps in use at construction site.

FIGURE 30.32 Tremie being placed in position for use.

High-quality architectural concrete can be obtained when placing concrete with trucks, tremies (Figure 30.32), buckets, or even wheelbarrows, provided proper procedures are followed. When concrete is placed directly from trucks or through tremies, the free fall should be limited to less than 5 ft (1.5 m). Tremies can be made of either sheet metal or reinforced plastic with a rectangular cross-section. Minimum inside dimensions would be 4×16 in. (100×400 mm). There must be sufficient space between reinforcing bars if a tremie is to be used. The flow of concrete from a truck or tremie must be directed within the reinforcing cage to ensure minimal bounce or deflection of the concrete off steel, conduit, or other obstructions that cause splatter or segregation of the mix. Splatter on the formwork above the level of plastic concrete can harden and cause a surface blemish that is difficult to remove. This is especially serious in finishes having a light or smooth texture.

FIGURE 30.33 Concrete pumped from the bottom up to minimize consolidation problems and bug holes. This hospital building was designed by Bertram Goldberg of Chicago.

Conveyors are useful when a low-slump concrete mix with a high coarse-aggregate proportion—2000 lb (900 kg) of coarse aggregate or more—is required. They are most often used when large floor (ceiling) and beam composite construction is required. Care should be taken with any conveying equipment to prevent contamination by nonarchitectural mixes and to prevent segregation of the mix being transported. If methods of conveyance are varied during the overall construction of architectural concrete, the uniformity of the finish surface color may be affected. When conveyors are used, they should have a high speed and have a discharge end that is easily movable to permit proper concrete mix distribution.

Concrete pumps must be rated on their ability to move concrete having a low w/c ratio that meets the architectural requirements of the project. Several pumps today have 5- or 6-in. (125- or 150-mm) lines that can handle most architectural concrete mixes. To prevent concrete consolidation problems in the walls and minimize bug holes, one contractor elected to pump walls from the bottom up. Pumping ports were installed in the wall forms 12 in. (302 mm) from the bottom and on 4-ft (1.2-m) centers along the steel forms. A superplasticizer was used to allow for 8- to 10-in. slumps (Figure 30.33). These serpentine architectural cast-in-place walls later had a white coating applied to their surface. In addition to cast-in-place concrete, battery and other vertical forms for precast products have been pumped from the bottom up. Use of a superplasticizer admixture can help the concrete to be pumped while maintaining the required w/c ratio. Variations in w/c ratio will change the color of the exposed architectural surface. When using a concrete pump, the first 1/4 yd³ (0.2 m³) should be wasted or utilized elsewhere, not in the architectural forms. It takes a certain amount of cement paste to coat the inside of the pump and hoses leading to the placement location. An alternative would be to initially charge the pump with a

FIGURE 30.34 Adjacent concrete walls from two separate days' placement showing the impact of pumping concrete directly without wasting first 1/4 yd³ (0.2 m³) to coat the pump and hoses.

high-cement grout mix prior to placing the regular concrete. Failure to do one or the other will result in a higher w/c ratio at the point of initial discharge and unsightly discoloration (Figure 30.34). The more uniform the w/c ratio, the greater the uniformity of the color and texture.

The depth of the layers of concrete placed and consolidated depends on the width of the forms, the amount of reinforcing present, the concrete placement method, and the timing required. Each new concrete lift should cover the previously placed concrete within 20 minutes. Substantial lift or pour lines may result when a 45-minute delay in placement of fresh concrete occurs. Fresh concrete is usually placed in lifts of no less than 18 in. (450 mm) and no more than 30 in. (750 mm). The surface of each lift should be fairly level so the vibrator does not have to move the concrete laterally. Lateral movement can cause segregation, leading to honeycomb or other surface blemishes. Concrete should be placed continuously at close intervals. A vibrator should be operated at the point of deposit during all concrete placement.

30.7.4 Concrete Consolidation

30.7.4.1 General

The most important single skill in architectural concrete involves the selection and operation of the vibrator. In Europe, vibration operation is recognized as being all important to good concrete work, and skilled vibrator operators are the highest paid workers on concrete crews. All too frequently in the United States, the vibrator operator is one of the most unskilled and untrained members of the concrete crew, often being picked for having a strong back rather than knowledge of concrete consolidation. A vibrator not only consolidates the concrete for maximum density but also internally blends the different lifts of concrete together into a single solid mass with few bug holes and no lift lines on the finished exposed surfaces.

30.7.4.2 Equipment

All too often vibrators are selected on the basis of their price or maintenance records. Instead, selection should be based on the following vibrator qualities (ACI Committee 309, 2005; Shilstone, 1972c):

- *Frequency* is the ability to fluidify the mix based on the number of times per minute the head moves from side to side.
- *Amplitude* is the ability to kick the mix into place. Amplitude is the measured distance of the head when it goes from side to side as measured from its neutral axis. An increase in amplitude results in an increase in the effective radius of action.

- *Power* is the ability to maintain vibration under load.
- *Size* is the ability to overcome the resistance of the concrete mix particles to movement. Use the largest diameter head permitted by the form dimensions and the spacing between reinforcement.

The high frequency of the vibrator alone will not work. If the power is constant and the frequency is increased, the amplitude decreases because the head does not have the time to travel as far as it did at lower frequency. If the power source is increased, the head has a greater amplitude, provided the frequency is not simultaneously increased. Larger vibrators provide more mass in the head. The larger mass head is necessary to provide the impulse to drive the concrete effectively into the intricacies of the form. A high-frequency, high-amplitude, high-powered vibrator moves to such a degree that it creates a churning action within the concrete mass. This is the type of vibrator necessary to combine two lifts of concrete into one. Achievement of void-free surfaces favors a higher-frequency vibrator.

Internal vibrators are generally referred to as *immersion*, *poker*, or *spud vibrators*. One of the most commonly used types is the flexible-shaft type, where the electric motor is outside the vibrator. A flexible shaft leads from the motor into the vibrator head, where it turns the eccentric weight. A universal 120-volt, single-phase, 60-Hz (cycles per second) motor is used, and the frequency of this vibrator when operating in air is quite high—in the range of 12,000 to 17,000 vibrations per minute (200 to 283 Hz) (the higher values are for smaller head sizes). Because of this high speed and the heat developed, the vibrator may burn up if operated carelessly outside the concrete; however, when the vibrator is operating in the concrete, the motor is under load and the frequency is generally reduced by about one fifth.

The electric motor-in-head vibrator type has the motor in the vibrator head, as the name implies. Most motor-in-head vibrators are high-cycle units. This means that a 180 high-cycle current is required for their operation instead of the usual 60-cycle commercial power. These vibrators use induction motors and operate at a frequency in concrete of about 10,000 vibrations per minute (vpm); this is only about 5% less than their free speed (speed in air). The high-cycle current is obtained by passing commercial power through a frequency converter or through the use of a special generator. Motor-in-head vibrators operating on a 60-cycle current with a universal motor are also available, but they have less capability than high-cycle units. The electric motor-in-head vibrators are generally at least 2 in. (50 mm) in diameter. When using electric vibrators, all power cables and connectors should be kept in good condition. Vibrators should not be lifted or carried by the electric cables. Sharp bends should be avoided in the shafts of flexible-shaft vibrators. When vibration is finished for the day, vibrators should be cleaned and concrete spills removed. It may be desirable to cover form vibrators to keep concrete from dropping on them, but not in such a way as to interfere with air cooling. Whether the consolidation equipment provides internal or external vibration, or a combination of both, its frequency and amplitude should be designed, tested, and proven for the volume, configuration, and placing technique of the product and the proportioning and consistency of the concrete for that product.

Because internal vibrators are used in wet (conductive) locations, all electric units should be grounded to the power source. Generator sets supplying power should also be grounded to maintain continuity of the grounding system. Units operating at less than 50 V or that are protected by an approved double-insulation system are excepted from the grounding system. In the United States, electric vibrators are subject to the National Electric Code, Article 250-45. External vibrators may be divided into form vibrators, surface vibrators, and vibrating tables. Form vibrators are external vibrators attached to the outside of the form or mold. They vibrate the form, which in turn transmits the vibration to the concrete. Extremely rugged forms are required where high-amplitude vibration is used. The effective penetration of the vibrations into the concrete ranges from 8 to 24 in. (200 to 600 mm). It may be necessary to supplement a form vibrator with internal vibration for sections thicker than 12 in. (300 mm) or higher than 4 ft (1.2 m). Rotary-type vibrators are preferred because reciprocating types are very hard on molds. Rotary-type vibrators may be operated pneumatically, electrically, or hydraulically. In the reciprocating type, a pneumatically driven piston is accelerated in one direction, stopped (by striking against a steel plate), and then accelerated in the opposite direction. These vibrators produce impulses acting perpendicular to the mold with frequencies usually in the range of 1000 to 5000 vpm (20 to 80 Hz).

In the pneumatically and hydraulically driven rotary-type models, centrifugal force is developed by a rotating cylinder or revolving eccentric weight. These vibrators generally work at frequencies of 6000 to 12,000 vpm (100 to 200 Hz). The frequency may be varied by changing the air pressure, usually by adjusting the air-supply valve or the fluid pressure on the hydraulic models. The amplitude and centrifugal force may be varied by changing the eccentric weight. The hydraulic models are driven by a hydraulic motor that turns an eccentric weight on a shaft. The advantage of this type of vibrator is the combination of an extremely low noise level, similar to an electric motor, with an infinitely variable speed. The unit can be locked into a specific frequency by use of a flow control. The wise contractor also has a spare for each type of vibrator available at the site in case of breakdown. If 180-cycle generators are used to power the vibrators, then two generators should be available at the site.

30.7.4.3 Internal Vibration

Internal vibration is recommended for all standard member cross-sections. The vibrator should be inserted vertically at uniform spacing over the entire area. The vibrator operator should be trained never to force the vibrator into a lift, as doing so produces voids in the earlier lift. Let the vibrator sink rapidly into the concrete to the bottom of the lift, but not less than 6 in. (150 mm) into the preceding lift, if there is one. With rapid penetration, the concrete is moved upward and outward, which drives the air and water ahead of the concrete and facilitates its escape to the top of the form surface. Because compaction does not occur below the tip of the vibrator, it is imperative for the operator to allow the vibrator to sink rapidly by its own weight into the preceding lift. If the first lift has partially set before the second is placed, it is practically impossible to blend the two layers. Unattractive lift lines and possible honeycomb will result.

The vibrator should be withdrawn slowly upward at the rate of about 2 in./sec in a slow churning (up-and-down) motion. Vibrator surge is always upward and generally at a 30° angle from the horizontal. The distance between vibrator insertions should generally be about 18 in. (depending on the properties of the mix and vibrator being used); the area visibly affected by the vibrator should overlap the adjacent just-vibrated area by a few inches. Vibrator insertions should be no farther apart than twice the radius of influence. Even the largest head vibrators have a radius of influence of 10 in. or less.

For architectural concrete, it is best to have two vibrators and two operators consolidating the concrete. The first operator is stationed at the point of deposit, where that vibrator is operated continuously. The second vibrator is used to slowly blend concrete, eliminate lift lines, and send entrapped air and water up along the form face and out of the concrete mix (Figure 30.35). When the vibrator head begins to emerge from the concrete, be sure the operator understands that it must be removed from the concrete quickly or else air will be drawn down between the concrete and the form. At no time should the head of the vibrator be half in and half out of the concrete. When that happens, immediately fully extract the vibrator from the concrete. Movement of the vibrator should not cease or pause while it is in the concrete. Constant manipulation is necessary to prevent the possible formation of harmonic motion, which could distort or deflect the form or cause failure in the form. The very least that can happen under these circumstances is paste leakage, honeycombing, or entrapping air on the form face.

Sometimes it is practical to insert a small vibrator between the reinforcement and the form face. In such cases, the vibrator should be rubber tipped; even so, any contact with the form should be avoided if at all possible because this might mar the form, disfigure the surface, and result in a darker color or leave vibrator paste marks in an exposed-aggregate surface (Figure 30.36). This entire procedure is dangerous. Actually, at no time should the head of an internal vibrator come in contact with the forms. The vibrator should be kept just within the steel reinforcing and be inserted no closer than 3 in. (75 mm) from the form on the side of the steel away from the form face.

For dry mixes, where the hole around the vibrator does not close during withdrawal, reinserting the vibrator a few inches away may solve the problem. While stiff mixes are to be encouraged, overly dry mixes may result in poor consolidation (honeycomb or excessive entrapped air) and should be avoided. Where air voids in formed surfaces are excessive, the distance between vibrator insertions should be reduced to about 12 to 15 in. (300 to 375 mm).

FIGURE 30.35 First operator is vibrating concrete at point of deposit; second operator is blending concrete to eliminate lift lines and minimize bug holes.

FIGURE 30.36 Grout lines on exposed face of architectural concrete due to an internal vibrator touching the side of the form during concrete consolidation.

Form liners have more surface area than flat forms, and they require greater internal vibration. Architectural concrete will normally require at least twice and maybe three times as much vibration and compaction effect as regular structural concrete. Sometimes very harsh mixes, such as those with gap

FIGURE 30.37 Concrete wall placed with a superplasticizer in the mixture and no internal or external vibration; settlement lines occurred at all horizontal reinforcing locations.

grading, are used to produce special architectural effects. These also require more powerful vibrators and longer vibration times. The contractor should be sure to choose a sufficiently large vibrator and see that vibration insertions are placed closely enough to consolidate all concrete. The vibration should be terminated when the mortar level reaches the top of the aggregate to minimize mortar lenses between lifts.

Superplasticized admixtures have changed the vibration techniques used in architectural concrete mixes. Superplasticized mixes require less vibration than standard mixes that do not include a superplasticizer admixture. When superplasticizers were first introduced, the literature stated that no vibration was required. This was a mistake, and several contractors unfortunately believed the technical data. Neither internal nor external vibration was used in placing the concrete. The results were disastrous; settlement cracks occurred at all horizontal reinforcing steel locations (Figure 30.37). It is virtually impossible to overvibrate a well-designed mix; however, it is possible to overvibrate a concrete mix containing a superplasticizer admixture. Overvibration of mixes containing superplasticizers may cause segregation, and the excess mixing action may entrap air or water, which will result in bug holes.

Lightweight concrete behaves differently from hard-rock concrete. Because of its lack of particle weight, it presents great problems for compaction and has a tendency to float. Considerably more surface blow holes should be expected with lightweight concrete; where these are not acceptable, lightweight concrete should not be used.

30.7.4.4 Form Vibration

Form vibration is recommended in areas inaccessible to internal vibration or where full floor height steel or reinforced plastic forms are used. External vibrators loosen joints in wood forms, causing grout leakage and honeycomb and therefore are not recommended for this use. Forms for external vibration must stand up under the repeated, reversing stresses induced by vibrators attached to the form. External vibration of forms improves surface quality, but the additional stressing of forms and liners can shorten their life. Form vibrators must be capable of transmitting the vibration more or less uniformly over a considerable area.

The form should have adequate skin thickness and suitable stiffeners. The vibrators should be rigidly attached to the form. Special attention should be given to form tightness to prevent grout leakage. Trials should be made with form vibrators prior to their large-scale use. These trials should simulate the forming conditions to be encountered on the structure. The size and spacing of form vibrators should be such that the proper intensity of vibration is distributed over the desired area of form. The spacing is a function of the type and shape of the form, depth and thickness of the concrete, force output per vibrator,

workability of the mix, and vibrating time. Current knowledge is inadequate to provide an exact solution to this complex problem (ACI Committee 309, 2005).

The recommended approach is to start with a spacing generally in the range of 4 to 8 ft (1.2 to 2.4 m). If this pattern does not produce adequate and uniform vibration, the vibrators should be relocated as necessary until proper results are obtained. Achieving the optimum spacing requires knowledge of the distribution of frequency and amplitude over the form and an understanding of the workability and compactibility of the mix. The frequency can readily be determined by a vibrating reed tachometer; however, the small amplitudes associated with form vibration have been difficult to measure in the past. Inadequate amplitudes mean poor consolidation, while excessive local amplitudes are not only wasteful of vibrator power but can in some cases also cause the concrete to roll and tumble so it does not consolidate properly. Moving one's hand over the form will locate areas of very strong or weak vibration (high or low amplitude) and dead spots.

Concrete compacted by form vibration should be deposited in layers usually 10 to 15 in. (250 to 400 mm) thick. Each layer should be vibrated separately. Vibration times are considerably longer than for internal vibration, frequently as much as 2 minutes, and possibly as much as 30 minutes or more in some deep sections. It is desirable to be able to vary the frequency and amplitude of the vibrators. On electrically driven external vibrators, amplitudes can be adjusted to different fixed values quite readily. On air-driven external vibrators, the frequency can be adjusted by varying the air pressure, and the amplitude can be changed by changing the eccentric weight. Because most of the movement imparted by form vibrators is perpendicular to the plane of the form, the form tends to act as a vibrating membrane, with an "oil-can" effect. This is particularly true if the vibration is of the high-amplitude type and the plate is too thin or lacks adequate stiffeners. This in-and-out movement can cause the forms to pump air into the concrete, especially in the top few feet (50 to 100 cm) of a wall or column lift, creating a gap between the concrete and the form. Here, there are no subsequent layers of concrete to assist in closing the gap. It is therefore often advisable to use an internal vibrator in this region. Form vibration during stripping is sometimes of benefit. The minute movement of the entire surface of the form helps to loosen it from the concrete and permits easy removal without damage to the concrete surface.

30.7.4.5 Revibration

The lift should be revibrated after initial consolidation with slow withdrawal of the vibrator head to draw out as many of the air bubbles as possible. The vibrator used to remove air bubbles from the top lift can be of lesser power or a smaller size than that used to initially consolidate the concrete. The usual high-energy vibrators have a tendency to churn air into the top lift of the concrete. This is the area where air and water pockets are most prevalent. If the architectural concrete mix is a properly designed low-slump mix, do not worry about overvibration. Revibration, after bleeding is substantially complete but before initial set, can be used to further densify the concrete and reduce air and water pockets against the form and exposed concrete face. Revibration can be accomplished any time the running vibrator will sink of its own weight into the concrete and liquefy it momentarily. It will accomplish most if it is done as late in the process as possible. Revibration generally results in improved compressive and bond strength, release of water trapped under horizontal reinforcing bars, minimized leakage under form bolts, and the removal of additional air voids. The greatest benefits are obtained for wetter concrete mixtures. Revibration should not be used where harsh gap-graded mixtures have been used to produce exposed-aggregate surfaces.

30.7.4.6 Spading

Spading may be employed in conjunction with internal or external vibration to improve finish surfaces. A flat, spade-like tool or a large plastic sail batten is repeatedly inserted through the top two lifts of concrete and withdrawn from the concrete adjacent to the form. This forces the coarse aggregate particles away from the form face and assists the air bubbles in their upward movement toward the top surface (ACI Committee 303, 2004). The spade, regardless of type, must be inserted often enough to cover the entire area of the form surface. Sometimes a wooden 1 × 4-in. (25 × 100-mm) or 1 × 6-in. (25 × 150-mm) board with a pointed chisel end is used, but better results have been obtained with a plastic sail batten.

Spading is usually done in conjunction with revibration by internal or external vibrators. The top lift must be quickly revibrated to close any gaps left by the spading. Although it is a laborious operation, the results can be worthwhile if spading is properly utilized. In addition to spading and revibration, pounding the outside of the forms with wooden mallets or a steel plate attached to an impact hammer, working from the bottom of the form upward, can release air bubbles and improve the concrete surface.

30.7.5 Curing

30.7.5.1 General

The method and period of curing should be consistent to produce a uniform concrete surface without stains, discoloration, drying, or plastic shrinkage cracks. Curing materials or methods should not allow one section of architectural concrete to cure or dry out faster than other sections, as this may produce color variations in the finish surface. Proposed methods should be tried on the site-cast mock-up to determine any adverse effects. Curing involves maintaining a satisfactory moisture content and temperature in the architectural concrete to produce the final qualities desired for both texture and durability of the surface. Unless early stripping is necessary to achieve a specific texture, concrete strength for removal of the forms is usually 2000 psi (13.8 MPa). The stripping strength is generally set by the design structural engineer. Freshly deposited and consolidated concrete should be protected from premature drying and extremes of temperature. The curing period of concrete that is of significant interest is during the early stages of strength development, from initial set until the concrete has reached the design strength appropriate for stripping of the forms. It is not necessary to wait for the mix water to finish bleeding to the surface before initiating the curing and protection of finish surfaces.

30.7.5.2 Curing in the Forms

Nearly all beams, columns, and undersides of slabs receive their curing by being left in the forms. To prevent staining caused by the type of form material, seal the forms with a liquid sealer prior to use, following the manufacturer's instructions. For vertical surfaces, the easiest thing is to leave the forms in place and keep them supplied with additional moisture through soaker hoses or other methods. Early removal of forms and application of curing compounds is generally unsuccessful for architectural concrete, although it is standard procedure for structural concrete. Curing compounds will usually stain the surface; for example, polyethylene stains the concrete a whitish color. Concrete in the form should be maintained at a temperature of not less than 50°F (10°C) during the curing period. In cold climates, the contractor may be required to use insulated forms to utilize the heat of cement hydration to maintain the temperature necessary during curing. The contractor may also have to provide heat (if necessary to maintain minimum temperatures and to minimize loss of moisture).

30.7.5.3 Moist Curing

Flat surfaces can be cured by ponding with the use of perimeter barriers and continuously operated sprinklers; however, the runoff water may create other problems at the project. Curing water should be checked for staining materials such as iron, which may cause rust stains, and the water should be uniformly applied to achieve uniformity of color. Flat surfaces can also be cured with the forms left on and the top surface covered with paper, polyethylene, or clean flannel. Burlap is dirty, can leave residual stains, and is generally not kept continuously wet. It may be necessary to erect wind breaks out of properly supported plastic sheets or temporary plywood walls. For vertical and other formed surfaces, after the concrete has hardened and while the forms are still in place, water should be applied so it runs down the inside of the form if necessary to keep the concrete uniformly wet. Immediately following form removal, the surface should be kept continuously wet with water spray or water-saturated fabric for a period of 5 days. Extending the curing period beyond 7 days does not produce additional beneficial effects, except in areas of very low humidity. Water curing has been found to reduce the possibility of cracks forming, to lighten dark blotchiness, and to create better uniformity of color. Uniformity of water application is important to obtain uniformity of color. If surface retarding agents are to be used,

water curing should be delayed until after the surface treatment has been accomplished. Rapid surface drying can lead to color variations. The contractor must have an adequate crew and all the required equipment prepared so placement, finishing, and curing can proceed without interruption and as rapidly as possible.

30.7.5.4 Membrane Curing

Liquid curing compounds may cause discoloration or staining and prevent the bond of any repairs or permanent coatings that may be needed. Curing compounds should only be used on the back of walls where the surface is not exposed or where the surface is to be removed by acid etching, sandblasting, or tooling. Manufacturers should be consulted as to the rate of coverage and the effect that their compound has in the above respects. This type of cure should be thoroughly evaluated on the preconstruction mock-up (ACI Committee 303, 2004). When used, membrane-curing compound should cover the entire surface to be cured with a uniform film that will remain in place without gaps or omissions. Areas with incomplete coating cover should be recoated. If a curing membrane is to be used, it is preferable to use an inorganic material such as sodium silicate. Organic curing compounds discolor after prolonged exposure to sunlight. The briefer the interval between stripping the form and applying the curing compound, the better, but the interval should be kept uniform from form to form to minimize color variation in the concrete. Curing compounds should be applied to the top of a wall as soon as floating is completed. Sodium silicates are especially useful for curing tops of walls because they do not break the bond between concrete and steel if sprayed on reinforcement and they do not interfere with subsequently applied cementitious toppings. Also, the sodium silicates fill the gap at the top of a wall where lower pressure compresses the plastic liner less and results in a slightly thinner wall section. In addition, sodium silicates consume free lime, greatly reducing the potential for efflorescence.

30.7.5.5 Hot-Weather Curing

The time between placing architectural concrete and initiation of curing is most critical in hot, dry, or windy weather. To minimize variations in color due to nonuniform drying and to prevent plastic shrinkage cracking, curing should commence as soon as practical (ACI Committee 303, 2004). To minimize drying shrinkage, it may be necessary to erect wind breaks out of properly supported plastic sheets or temporary plywood walls.

30.7.5.6 Cold-Weather Curing

Thermal curing is important during cold weather. If concrete forms are removed during cold weather while the concrete is still warm, rapid cooling of the concrete surface can result in crazing cracks. If steel forms are used, thermal cracking can occur without removing the forms. The problem is compounded if the concrete is to receive a sandblasted finish, which further opens the cracks. To minimize thermal cracking and crazing, leave forms in place until the concrete has cooled enough and gained sufficient strength to reduce thermal shock. If steel forms are used or if mass concrete is involved, use insulating blankets on the forms to slow heat loss. Do not use insulating blankets directly on the concrete as this can result in blotchiness where the blankets touch the concrete.

30.7.6 Protection

All freshly placed concrete should be protected from the elements and from any defacement due to subsequent building operations. One of the most common problems is rain or construction runoff water moving across rebar or other stored materials and then flowing down the face of the exposed architectural concrete. Another cause of rust staining is the use of steel scaffolding. On all architectural concrete contracts, nonferrous scaffolding should be used. If steel scaffolding is necessary, it should be maintained with all surfaces painted. Stain removal is discussed in the Portland Cement Association's publication *Removing Stains and Cleaning Concrete Surfaces* (PCA, 1988). Corners, edges, and other surfaces vulnerable to damage should be protected with suitable guards or barricades until the project is complete.

30.8 Production and Installation of Precast Elements

30.8.1 Production

Production of architectural precast has progressed from reliance on individual craftsmanship to a well-controlled and coordinated production-line method with corresponding economic and physical improvements. The contract documents should make reference to PCI's *Manual for Quality Control for Plants and Production of Architectural Precast Concrete Products* (PCI, 1996) as the industry guideline for production. The general objective of this standard is to define the required minimum practices for production and for a program of quality control to monitor the production; therefore, a performance specification based on this publication will ensure a quality product.

30.8.2 Coordination

Even if the quality of the precast concrete components delivered to the job site is good, the success of the entire project is dependent on the quality of workmanship of the erector. A poor erection job can detract not only from the performance of the structure but also from the appearance of even the best designed precast concrete project. The erector should assist the general contractor/construction manager (GC/CM) in taking the lead on a construction site to help solve problems before they occur by coordinating efforts with other participants on the project. The responsibility for the erection of precast concrete may vary as follows:

- The precast concrete manufacturer supplies the product already erected, either by in-house labor or by an independent erector.
- The manufacturer is responsible only for supplying the product, free-on-board plant or jobsite. Erection is done either by the general contractor or by an independent erector under a separate agreement with the general contractor and/or owner.
- The products are purchased by an independent erector, who has a contract with the general contractor or owner to furnish the complete precast concrete package.

On projects where the precast concrete manufacturer does not have the contractual obligation for the erection, it is extremely desirable for the manufacturer to assign a representative to observe and report on planned erection methods. Regardless of contractual obligations, it is recommended that the precast concrete manufacturer maintain adequate contact with the firms responsible for both transportation and erection to ensure that the precast concrete units are properly handled and erected according to the design and project specifications.

The GC/CM is normally responsible for the project schedule and dimensions and coordination with all other construction trades. Relative to erection of precast concrete the GC/CM, in conjunction with the precaster, should:

- Be responsible for coordinating all information necessary to produce the precast concrete erection drawings. A prejob conference should be held as soon as possible after award of the precast concrete contracts. This meeting should consider erection sequencing, weight and size limitations, special rigging, and guy and bracing scheme information. This information should be communicated to the precaster's design engineer. Upon receipt of this information, the design engineer should, if necessary, develop a bracing sequence to maintain stability of the structure during erection in conjunction with the erector and engineer of record. Limitations may state, for example, that loading of the structure should be balanced, requiring that no elevation be erected more than a stated number of floors ahead of the remaining elevations, or limitations may involve the rigidity of the structure, requiring that walls should not be erected prior to the completion of floors designed to carry the lateral loads. In steel frames, it should be determined how far in advance final frame connections must be completed prior to panel erection. Particular consideration should

be given to deflection and rotation of the supporting structure due to the precast and other superimposed loads. For concrete frames, what strength of concrete is required should be determined prior to imposing loads of the precast concrete panels. The frame designer should also recognize that connections between panel and frame impose concentrated loads on the frame and that these loads may require supplementary local reinforcing. In the case of multistory concrete frames, consideration should be given to the effects of frame shortening due to shrinkage and creep.

- Review and approve or obtain approval for all erection drawings and design.
- Be responsible for the coordination of dimensional interfacing of precast concrete with other trades.
- See that proper tolerances are maintained to guarantee accurate fit and overall conformity with precast erection drawings.
- Be responsible for providing and maintaining clear, level, well-drained unloading areas and road access around and into the structure to such a degree that the hauling and erection equipment for the precast concrete units is able to operate under their own power. Erection equipment should be able to handle units directly from the transportation equipment.

Sequencing is of the utmost importance for facilitating erection of the structure. Prior to the manufacture of precast members, the erection and job sequence should be mutually agreed upon by the GC/CM, precaster, and erector. To avoid excessive erection costs, efforts should be made to allow a unit to be handled in one motion from unloading to positioning. When a sequence has been agreed upon, it should be strictly adhered to unless severe unforeseen problems dictate a sequence change.

30.8.3 Field Verification and Layout

Surveys should be required before, during, and after erection:

- Before, so the starting point is clearly established and any potential difficulties with the support structure are determined early
- During, to maintain alignment
- After, to ensure that the products have been erected within tolerances

The benefits of surveying and laying out the support location prior to erection include: (1) when an error is found it can be corrected prior to starting erection; (2) costly erection delays for crane and crew are avoided if everything fits; and (3) layout crews may find errors on the shop drawings, which, if caught in time, can reduce costly corrections and minimize delays. It is the responsibility of the GC/CM to establish and maintain, at convenient locations, control points, benchmarks, and lines in an undisturbed condition for the erector's use until final completion and acceptance of a project. If the building frame is not precast concrete, then the benchmarks and building lines should be provided by the GC/CM at each floor level. Work points should also be provided for angled and curved building elevations. The erector should be advised by the GC/CM of any known discrepancies in field location, line, or grade and be provided with suitable work areas for layout.

Prior to beginning erection and the scheduling of delivery and handling equipment, a field check of the project should be made by the erector to ensure that foundations, walls, and structural frames are suitably constructed to accept the precast concrete units. This should include a field check of the work affecting the erection contract, including the location, line and grade of bearing surfaces, notches, blockouts, anchor bolts, cast-in-place or contractor's hardware (miscellaneous iron), a check on dimensional tolerances, and a check of all overhead electrical lines. The objective of this survey is to ensure that the areas to receive the precast concrete are ready and accessible to the erector and that the precast units will fit.

Survey notes should be kept of all discrepancies that exceed specified tolerances. Any discrepancies between site conditions and the architectural, structural, and erection drawings that may cause problems during erection, such as structural steel out of alignment, anchor bolts or dowels improperly installed,

errors in bearing elevation or location, and obstructions caused by other trades, should be noted in writing and sent to the precast concrete manufacturer and GC/CM. Erection should not proceed until discrepancies are corrected by the GC/CM, or until erection requirements are modified and reviewed by the design engineer. Verification of remedial work should be the responsibility of the GC/CM. The erector should return to the site for a final survey after all necessary corrections of site conditions have been made by the GC/CM and before any erection is started.

Working from the control points, benchmarks, and lines established by the GC/CM, the erector should establish offset lines and elevation marks as required for use at each floor level. Precast concrete members must be installed to accurate lines and grades to ensure both proper performance and correct relationships with adjoining work. It is the layout crew's duty to mark the locations to receive the precast concrete units so the erector can place them with a minimum of measuring or moving to get them into final position. The erector should establish joint locations prior to actual product installation. This will keep the differential variation in joint width to a minimum, as well as identify problems caused by the building frame, columns, or beams being out of dimensional or alignment tolerance. The layout crew should be kept well ahead of erection so if corrections are required there is adequate time for the design, approval, fabrication, and installation of repairs so as not to hinder the process of erection.

30.8.4 Delivery

Factors to be considered when delivering precast members from the plant to the job site are type, size, shape, and weight of the member; type of finish; weather; road conditions; method of transportation; type of vehicle; routing; distance to the job; and job-site conditions. The shipper, not necessarily the precast concrete manufacturer or erector, is responsible for safe delivery of precast members. The precast concrete manufacturer, shipper, and erector should develop clearly defined acceptance procedures to avoid later disagreement concerning damage. The precast concrete manufacturer or erector should advise the shipper of any special situations along possible routes and at the job site to:

- Ensure safe transportation.
- Meet various governmental transportation regulations.
- Prevent or minimize in-transit damage with proper supports, frames, blocking, cushioning, and tie-downs. These materials are normally supplied by the precast concrete manufacturer and returned for repeat usage by the shipper. All blocking, packing, and protective materials must be of a type that will not cause damage, staining, or other disfigurement of the units. The blocking points and orientation of the units on the shipping equipment should be as designated on the shop drawings.
- Permit their removal from the load in proper sequence and orientation to minimize handling and possible damage to the product.
- Ensure that the product is oriented and loaded on the trailers so it can be erected without unnecessary offloading and rehandling; unloading of product on the ground is usually costly, creates site access problems for everybody, and often results in damage to the product.
- Ensure that sufficient product is delivered to the site in the prescheduled sequence to allow for orderly, efficient installation in the structure.

30.8.5 Connection Considerations

A certain amount of field adjustment at the connections is normal. Product tolerances make the possibility of a perfect fit in the field impossible. This is true when the precast concrete pieces join to each other and is even more true when the precast units must interface with other materials. Each industry has its own recommended erection tolerances that apply when its products are used exclusively. Hardware design for connections should take into account the tolerances for both the precast concrete components and the structure. These considerations may require clip angles and plates with slots or oversized holes to compensate for dimensional variation, field welding, or sufficient shim spaces to allow for elevation

variations. Sufficient minimum clearance between precast units and the structure must be provided to allow for product and erection tolerances. Hardware should be designed to compensate for additional stress at the maximum anticipated clearance. Hardware should also be designed to allow for movement in the building. Welded connections should only be used at one end of a panel; at the other end, slotted, bolted connections or other connection types that allow for movement should be used.

Field adjustments or changes in connections that could create additional stresses in the products or connections should not be permitted without approval by the architect or engineer. Particular care should be taken to prevent damage to the precast concrete unit when adjustments are being made to bring the unit into final position. Whenever possible, the connections should be completed in such a manner to permit operations to take place on the top side of erected members rather than from below where ladders or scaffolds are required, especially for welding. The type of equipment necessary to perform operations such as welding, post-tensioning, or pressure grouting should be considered. Operations that require working under a deck in an overhead position should be avoided, especially for welding. Alternatives to any erection techniques that require temporary scaffolding should be considered. Room to place wrenches on nuts and turn them through a large arc should be provided for bolted connections. Foundation piers should extend above grade so the anchor bolts can be adjusted during erection and the base plate need not be grouted in a hole, which can fill with water and debris. Properly drypacking column or wall-panel bases in a narrow excavation is difficult.

It is desirable to have connections that are designed so the erector can safely secure the member to the structure in a minimum amount of time without totally completing the connections. If necessary, temporary bracing or connections should be used with final adjustment and alignment in all directions relative to the structure and adjacent components completed independently of crane support. This allows the hoisting device to begin placing the next unit while connections on the first are being completed. The temporary connections should not interfere with or delay the placement of subsequent members. The temporary connections may have to be relieved or cut loose prior to completion of the permanent connections.

Connection details should allow erection to proceed independently of ambient temperatures and without temporary protective measures. Materials such as grout, drypack, cast-in-place concrete, and epoxies require protection or other special provisions when placed in cold weather. Also, welding is slower when the ambient temperature is low. If the connections are designed so these processes must be completed before erection can continue, the cost of erection is increased and delays may result.

The supply of erection hardware—that is, the loose hardware required in the field for final connection of precast members—should normally be the responsibility of the precast concrete manufacturer. The responsibility for the supply of contractor's hardware to be placed on or in the structure to receive the precast concrete units depends on the type of structure and varies with local practice but in any case should be clearly defined in the contract documents. Hardware should be incorporated in the structure within the specified tolerances according to a predetermined and agreed-upon schedule to avoid delays or interference with the precast erection. Hardware should be maintained and suitably protected (such as capping of inserts and protection of threads) until used by the precast erector. At times, it may be necessary to modify connections in the field to accommodate unforeseen clearance problems or the work of other trades. The GC/CM should clear any modifications through both the precast concrete manufacturer and the designer to ensure proper performance of the connections.

30.8.6 Installation

Hoisting the precast pieces is usually the most expensive and time-critical erection process. Connections should be designed so each unit can be lifted, set, connected, and unhooked in the shortest possible time. Before the hoist can be unhooked, the precast piece must be stable and in its final position. Preplanning for the fewest, quickest, and safest possible operations that must be performed before releasing the crane will greatly facilitate erection. Bearing pads, shims, or other devices upon which the piece is to be set should be placed ahead of hoisting. Loose hardware that is required for the connection should be immediately available for quick attachment. In some cases, it may be necessary to provide temporary

fasteners or leveling devices, with the permanent connection being made after the crane is released; for example, if the permanent connection requires field welding, grouting, drypacking, or cast-in-place concrete, the use of erection bolts, C-clamps, guy lines, pins, or shims should be considered. These temporary devices must be given careful attention to ensure that they will hold the piece in its proper position during the placement of all other pieces erected before the final connection is made.

Shims are often used as spacers or as means of leveling or aligning adjacent components. They serve an interim or temporary load-transferring function. Unless such temporary loading of units has been specifically incorporated or allowed in the contract documents, the erector should be responsible for this temporary loading of the units. High-density plastic and steel shims are commonly used to attain the specified joint dimension. Shims should be placed away from the face of the unit to prevent spalling in case of excessive loading. Also, they should be recessed out of view as they can be unsightly and difficult to remove if exposed to view. Shims should be removed from joints of non-load-bearing units after connections are completed and before applying sealant, unless the shim material itself is readily deformable. If left in place, shims should be noncorrosive or protected so staining will not occur. For load-bearing units, the use of nonmetallic shims or bearing pads such as neoprene or plastic may be used where bearing pressures do not exceed the allowable concrete stresses and the potential risk of damage to concrete edges is negligible.

The indiscriminate use of shims, particularly steel shims, can sometimes lead to undesirable consequences; for example, steel shims have been used in conjunction with grouted joints in multistory bearing-wall construction. Even with well-compacted grout or drypack, the compressive modulus of the steel shim is six times that of the drypack; consequently, the grout will deform (compress) more readily than the shim. The principal load-transfer path will remain concentrated through the steel shim rather than distributed along the grout bed. High load concentrations at shims can cause spalling at panel surfaces or crack panels vertically.

Precast concrete units should be erected at locations shown on the erection drawings, within the allowable tolerances. They should be positioned so cumulative dimensional errors do not exceed allowable tolerances. Horizontal and vertical joints should be correctly aligned and uniform joint width maintained as erection progresses. The installation or prewelding of miscellaneous iron hardware should be performed prior to the start of erection, whenever possible, to minimize the cost of crew and equipment standby. All inserts for lifting and bracing should be filled immediately after units are erected to prevent staining from corrosion-sensitive inserts or water freezing in them. Wall panels should be rigged and hoisted on the structure near the final location and held in place until safely secured. Final alignment and final connections may be made at once or later by follow-up crew, depending on the type of connection.

The connections should allow for easy adjustment in all directions. Panels should be installed on a floor-by-floor basis, where feasible, to keep loading equal on the structure, or the designer of the structural frame should determine the degree of imbalanced loading permitted (the sequence should be shown on the erection drawings). Limitations may state, for example, that loading of the structure must be balanced, requiring that no elevation be erected more than a stated number of floors ahead of the remaining elevations, or limitations may involve the rigidity of the structure, requiring that walls not be erected prior to completion of the floors designed to carry lateral loads. Panels should be aligned to predetermined offset lines established for each floor level. This is important because of the drift of a high-rise structure caused by sun, wind, and eccentric loads and forces due to construction activity being performed by others. It should be determined how far in advance of precast concrete erection that final connections in steel structures must be completed and what the minimum concrete strength should be for cast-in-place structures prior to loading them with precast concrete units.

Consideration should be given to the number of floors the erector wants to erect in a structure on temporary connections before making final connections. This is especially important for grouted connections and cold-weather conditions. Precast spandrels usually extend from column line to column line at the building perimeter. They connect either at the columns or directly to the perimeter beams. Precautions should be taken against torsional rotation, due to eccentric loadings on perimeter beams, until final connections are made. Shoring may be required to assist in erection until connections are made.

FIGURE 30.38 Erection tolerances for architectural precast concrete wall panels.

Alignment and all connections should be made or the spandrels should be safely secured prior to releasing the load and disconnecting the rigging. On long spandrels, care should be taken to ensure that the spandrel is tied back at the center either through a temporary connection until a slab tie connection is made or with a permanent connection. Spandrels should be installed on a floor-by-floor basis, where feasible, to keep equal loading on the structure. Spandrels should be aligned to predetermined offset lines established for each floor level. Vertical dimensions between spandrels should be checked to ensure that the opening size is within allowable tolerance. When spandrel panels or column covers and mullions are interspaced with strips of windows to create a layered effect of glazing, precast, and glazing, the general contractor should work closely with the designer to arrive at interface details that can be built within the sequence of construction and that embody all the elements required of the exterior wall design.

30.8.7 Tolerances

Architectural precast concrete product tolerances should comply with the industry tolerances published in PCI MNL-117 (PCI, 1996). The recommended erection tolerances are shown in Figure 30.38. During wall-panel installation, priority is generally given to aligning the exterior face of the units to meet aesthetic requirements. This may result in the interior unit faces not being in a true plane. A liberal joint width should be allowed if variations in overall building dimensions are to be absorbed in the joints. This may be coupled with a closer tolerance for variations from one joint to the next for appearance purposes. The individual joint-width tolerance should relate to the number of joints over a given building dimension. For example, to accommodate reasonable variations in actual site dimensions, a 3/4-in. (19-mm) joint may be specified with tolerances of $\pm 1/4$ in. (± 6 mm) but with only a 3/16-in. (5-mm) differential variation allowed between joint widths on any one floor or between adjacent floors. Alternatively, a jog in the alignment of an edge may be specified. The performance characteristics of the joint sealant should also be taken into account when selecting a joint size.

Variations from true length or width dimensions of the overall structure are normally accommodated in the joints or, where this is not feasible or desirable, at the corner units, in expansion joints, or in joints adjacent to other wall materials. In a situation where a joint has to match an architectural feature (such as a false joint), a large deviation from the theoretical joint width may not be acceptable, and tolerance for building lengths will have to be accommodated at the corner units. Erection tolerances are of necessity largely determined by the actual alignment and dimensional accuracy of the building foundation, and frame. The general contractor is responsible for the plumbness, level, and alignment of the cast-in-place concrete foundation and structural frame (except for precast frames) including the location of all bearing surfaces and anchorage points for the precast concrete units. If the precast concrete units are to be installed reasonably “plumb, level, square, and true,” the actual location of all surfaces affecting their alignment, including levels of floor slabs and beams, the vertical alignment of floor slab edges, and the plumbness of columns or walls, must be known before erection begins.

The architect or engineer should clearly define in the specifications the maximum tolerances permissible in the foundation and building frame alignment and then should see that the general contractor frequently checks to verify that these tolerances are being held. In addition, the architect or engineer should ensure that the details in the contract documents allow for the specified tolerances. Lack of attention to these matters often necessitates changes and adjustments in the field, not only delaying the work but also usually resulting in unnecessary extra costs and sometimes impairing the appearance of the units and the completed structure.

With reasonable tolerances for the building frame established, it is equally important for the designer to provide adequate clearances (purposely provided space between adjacent members)—for example, between the theoretical face of the structure and the back face of a precast concrete panel—when detailing the panel and its relationship to the building structure. If clearances are realistically assessed, they will enable the erector to complete the final assembly without field altering the physical dimensions of the precast units.

A good rule of thumb is that at least 3/4-in. (19-mm) clearance should be required between precast members, except for flange-to-flange connections and connection of wall panels to precast members, where 1/2-in. (13-mm) clearance should be required with a 1-in. (25-mm) clearance preferred; 1 in. (25 mm) is the minimum clearance between precast members and cast-in-place concrete, and 2 in. (50 mm) is preferred. For steel structures, 1 in. (25 mm) is the minimum clearance between the back of the member and the surface of the fireproofing, and 1-1/2 in. (38 mm) is preferred. If no fireproofing is required on the steel, then a 1-in. (25-mm) minimum clearance should be maintained. At least a 1-1/2 to 2 in. (38 to 50 mm) of clearance should be allowed in tall structures regardless of the structural framing materials. The minimum clearance between column covers and columns should be 1-1/2 in. (38 mm), with 3 in. (75 mm) being preferred because of the possibility of columns being out of plumb or a column dimension interfering with completion of the connection. If clearances are realistically assessed, they will solve many tolerance problems. Where large tolerances have been allowed for the supporting structure, or where no tolerances for the structure are given, the clearance must be increased.

All connections should be provided with the maximum adjustability in all directions that is structurally or architecturally feasible. Where a 1-in. (25-mm) clearance is required but a 2-in. (50-mm) clearance creates no structural or architectural problem, the 2-in. (50-mm) clearance should be selected. Closer tolerances are required for bolted connections than for grouted connections. To accommodate any misalignment of the building frame, connections should provide for vertical, horizontal, and lateral adjustments of at least 1 in. (25 mm).

Location of hardware items cast into or fastened to the structure by the general contractor, steel fabricator, or other trades should be ± 1 in. (± 25 mm) in all directions (vertical and horizontal), plus a slope deviation of no more than $\pm 1/4$ in. (± 6 mm) in 12 in. (0.3 m) for the level of critical bearing surfaces. All bearing surfaces are not always level. These tolerances give an acceptable deviation. Connection details should consider the possibility of bearing surfaces being misaligned or warped from the desired plane. Adjustments can be provided with the use of drypack concrete, nonshrink grout, shims, or elastomeric pads if the misalignment from horizontal plane exceeds 1/4 in. (6 mm).

30.8.8 Protection of Work

All precast concrete should be furnished to the job site in a clean and acceptable condition and kept in such condition. The erector is normally responsible for any chipping, spalling, cracking, or other damage to the units after they are delivered to the job site and until they are erected and connected. The erector should take necessary precautions to protect the erected precast concrete and the work and materials of other trades from damage during erection. After the final erection of any portion of precast work to acceptable alignment and appearance, including completion of all connections and joints, the general contractor should assume responsibility for protection of the work. Any cleaning or repair of precast concrete work subsequent to installation or acceptance should be done by the erector or precaster, but under the responsibility of the general contractor. Specifications should state this responsibility clearly. It is impractical for the precaster or erector to police the work against damage by others after it is put in place. A carefully established and implemented program of protection and later cleaning should be in place for each job that is under the responsibility of the general contractor, who alone can control all the potential sources of damage.

At the end of each working day, measures may have to be taken to protect the installation from damage; for example, adequate temporary protection must be provided where precast units in partially completed buildings could be damaged by weather, such as water freezing in holes, pipe sleeves, and inserts. The GC/CM should provide and maintain temporary protection to prevent damage or staining of exposed precast concrete during construction operations after it has been installed. Rainwater or water from hoses used during the construction of the building can cause discoloration of the precast concrete units by first washing across other building materials (such as steel, concrete, or wood) and then across the precast units. Particular care should be taken to avoid allowing jobsite water to wash the units. Dirt, mortar, and debris from concrete placing should not be allowed to remain on the precast concrete and should be washed off immediately with clean water. The erector should protect adjacent materials, such as glass and aluminum, from damage from field welding or torch cutting operations; therefore, sequencing the work of other trades should be taken into consideration by the GC/CM to prevent such damage.

30.8.9 Sealants

Sealant life and performance are greatly influenced by joint design. For optimum performance and maximum life, the recommendations of the joint-sealant manufacturer should be followed. Joints between precast units must be wide enough to accommodate anticipated wall movements, and particular care must be given to joint tolerance in order for the joint sealant system to perform within its design capabilities. If units cannot be adjusted to allow for proper joint size, saw cutting may be necessary. When joints are too narrow, bond or tensile failure of the joint sealant will occur and adjacent units may come in contact with and be subjected to unanticipated loading, distortion, cracking, and local crushing (spalling). A good general rule is to erect precast units in such a manner as to provide 1/2-in. joints between units up to 15 ft long and a minimum of 3/4-in. joints for longer units. (Joint width should equal two to four times anticipated movement, depending on the properties of the specified sealant.) Corner joints should be 1 in. wide to accommodate the extra movement and bowing often experienced at corners. Sealants should not be installed in joints smaller than 3/8 in. wide by 3/8 in. deep. The required sealant depth is dependent on the sealant width at the time of application. The optimum sealant width-to-depth relationships are best determined by the sealant manufacturer. For a comprehensive discussion of joint sealants used between wall panels, refer to ASTM C 962 (ASTM, 1996). Sealants used for specific purposes are often installed by different subcontractors; for example, the window subcontractor normally installs sealants around windows, whereas a second subcontractor typically installs sealants around panels. The designer must select and coordinate all of the sealants used on a project for chemical compatibility and adhesion to each other. In general, contact between different sealant types should be minimized. The recommendations of the sealant manufacturer should always be followed regarding mixing, surface preparation, priming, application life, and application procedure. Good workmanship by qualified sealant applicators is the most important factor for satisfactory performance.

30.9 Finish Cleanup

30.9.1 Tie-Hole Repairs

Tie holes should be plugged to prevent corrosion of the tie and possible staining of the surface, except where stainless steel form ties are used (ACI Committee 303, 2004). The holes left in the surface of the concrete as the result of the form tie may be either small or large, depending on the type of tie used. In a rough-textured surface, small holes can be plugged flush with the surface and concealed. With smooth-surface concrete, the tie holes will be more apparent, and it is better to only partially fill the holes, leaving the holes as a part of the planned appearance. Care must be exercised to avoid smearing the fill material on the surface of the concrete. Materials used for plugging tie holes include Portland cement mortar, epoxy mortar, plastic plugs, precast mortar plugs, and lead plugs. The method should be carefully selected from among those that have shown no staining or discoloration tendencies in actual use. Mortar materials of a dry-tamp consistency and densely tamped into the hole will be less likely to smear on the surface than those of wet consistency. When Portland cement mortar is used, the tie hole should first be prewet with clean water, and then a neat cement slurry bond coat should be applied to the hole surfaces before they are filled with mortar. If epoxy mortar is used, it should be applied in accordance with the manufacturer's instructions, and a caulking gun should be used to inject it into the tie hole to prevent smearing it on the surface. Cleaning or removal of any fill material is difficult and will usually leave a stain on the surface. Plastic inserts provided by cone tie manufacturers can be wedged into the tie hole, leaving a standard predetermined recess. Lead plugs can be wedged into the hole by hammering. Sometimes the removable cone becomes embedded in the concrete due to form movement or leakage around the cone. It can be removed to produce a neat appearance by drilling out the cone with a diamond bit tool that conforms to the hole size. It may be economical to remove all cones in this manner to ensure neat, uniform holes. When tie holes have to be concealed rather than visible as part of the planned appearance, the repair procedure is similar to that required for blemish repair.

30.9.2 Repairs

A certain amount of repair of architectural concrete surfaces is to be expected (Ford, 1982). Blemishes that are beyond the limits established by the quality of the preconstruction mock-up must be repaired. Major repairs of cracks or honeycomb surfaces should not be attempted until an engineering evaluation is made to determine if a sound repair can be made or if concrete removal is required. The repair work should proceed as soon as possible after form removal using the materials and methods already accepted on the approved mock-up. The repair and the surrounding concrete will then age together, and the chance of color or texture variation will be minimized.

Prior to beginning any repair, the surface blemishes must be evaluated to determine if repairs should be attempted at all. Do not make surface blemishes worse. Too often, indiscriminate repair of architectural concrete surfaces results in accenting blemishes rather than improving them. Much of the skill in repair of surface defects lies in knowing what not to attempt. Repair work should be kept to a minimum. Small repairs can be treated by hand tooling or chemical treatment using bleaches, acids, or toners. Hand tooling refers to the use of needle scalers, chisels, bushhammers, or grinders. These tools are useful for eliminating or minimizing hard spots and discolored areas such as the dark lines associated with form-leakage points. Tools can also be effective in blending offsets and cold joints in combination with grout repairs. The importance of establishing a repair method before the need arises cannot be overstressed. Once proven acceptable on the mock-up, immediate repairs can be made without delay and with confidence in the final outcome.

Repair work for architectural concrete requires expert craftsmanship and careful selection and mixing of materials if the end result is to be structurally sound, durable, and aesthetically pleasing. Where adjacent acid-etching, sandblasting, tooled, or bushhammering treatments must be matched, experimentation should be performed on unimportant areas. Ingenuity may sometimes be required to establish methods and techniques that are as satisfactory as those in standard use. Excessive deviations in color and texture

of repairs from the surrounding surfaces may result in the architectural concrete or precast concrete not being approved until the variation is minimized. Light honeycomb areas, bug holes, pour lines, or cold joints when sufficient rock is in place can receive a grout patch mix without a cutting and drypack requirement. All that is necessary is to pre-wet the area to be repaired, along with the adjacent concrete, keeping it wet for at least an hour. Then, using a dense sponge float, scrub the predetermined grout mix into the voids between the coarse aggregate. It may be necessary to scrub in a second grout patch mix application to obtain a true flush surface. When the finish has exposed aggregate, just prior to initial set wash the concrete surface with a soft sponge or bristle brush, exposing the aggregate texture desired. Begin curing procedures immediately to ensure that the repair does not dry out too quickly and develop shrinkage cracks. Cure the repair a minimum of 3 to 7 days before attempting final texturing.

Where the surface blemish cannot be repaired by mechanical, chemical, or grout treatment, the area should be cut out using a pneumatic or hand-held chipping hammer. Edges of the cut area should be square and perpendicular or undercut to the face of the sound adjacent concrete to avoid any feather-edge repairs. In an exposed-aggregate area, cut irregularly to conceal the repair. In finishes involving a liner, cut along the texture lines. The procedure for repairs is as follows:

- After all adjacent finish texture and chipping is complete, remove loose particles and brush or blow all dust from the repair surface.
- Proportion the patch mix by weight according to the same proportions used in the concrete mix but substitute 5 to 50% of the gray or buff cement with white cement. The actual amount is based on tests to determine what is required to match the finish surface. A pigment or toner is sometimes used for a closer color match or when only white cement was used in the original mix design.
- Apply a 50% diluted coat of bonding material to the root of the repair area, being careful to avoid brushing or dripping it on any concrete surface to be exposed. This prevents loss of moisture from the patch mix while also improving bond.
- Use a wood or plastic trowel to fill the repair area with patch mix in layers 1/2 in. (12 mm) thick. Vibrate or tamp the patch mix manually to approximately the density of the existing concrete. Strike the area level; if, after initial set, the finish has exposed aggregate, brush the surface to match the surrounding area.
- Begin curing procedures immediately.
- Clean the area adjacent to the repair to remove laitance and to restore the original color and texture.
- After 3 to 7 days, add the final texture and thoroughly clean the repair area.
- After 28 days, the repair can be evaluated for acceptance when the finished surface is dry. Any repair should match adjacent surfaces in color and texture when viewed at a distance of 20 ft (6 m).

It is preferable that repairs not be made when direct sunlight is on the repair area. Temporary sunshades should be provided, especially during hot weather. Heat lamps or a small heated enclosure may be necessary to maintain a minimum 50°F (10°C) for curing repairs in cold weather. Repair and patching of precast concrete is an art requiring expert craftsmanship if the end result is to be structurally sound, durable, and pleasing in appearance. Responsibility for repair work is normally resolved between the precaster and the erector. Repairs should be done immediately following occurrence of damage; however, deciding when to perform the repairs should be left to the precaster, who should be responsible for satisfactory final appearance. Because the techniques and materials for repairing precast concrete are affected by a variety of factors including mix ingredients, final finish, size and location of damaged area, temperature conditions, age of member, surface texture, etc., precise methods for repair cannot be detailed here. See PCI MNL-117-96 (PCI, 1996) for guidance on repair techniques and materials.

Repairs should be done only when conditions exist that ensure that the repaired area will conform to the balance of the work with respect to appearance, structural adequacy, and durability. Slight color variations can be expected between the repaired area and the original surface due to the different age and curing conditions of the repair. Time will tend to blend the repair into the rest of the member so it will become less noticeable. After all repairs have been completed, the repairs should be coated with a silane or dilute (2 or 3% solids) solution of an acrylic sealer to minimize moisture migration into the

repair concrete. The acrylic sealer should not stain the concrete or leave a shiny surface. Even with proper consolidation, the repaired area is more porous than the original hardened concrete and will require this dilute sealer application.

30.9.3 Cracks

Small cracks, under 0.010 in. (0.25 mm), may not require repair unless failure to do so will cause corrosion of reinforcement. If repair is required to restore structural integrity for cracks that range in width from 0.003 to 0.015 in., they should be repaired with epoxy injection. Proper preparation of the crack area is very important. Form-release agents, efflorescence, grease, oil, dirt, or fine particles of concrete prevent epoxy penetration and bonding. Preferably, contamination should be removed by vacuuming or clean water flushing or a specially effective solvent, determined by prior experience or testing. The solvent is then blown out using compressed air or adequate time is provided for air drying. Cracks may be pressure injected through entry ports with a low-viscosity, high-modulus, 100% solid, two-component epoxy that will bond to a moist surface. It is usually impossible to completely remove moisture in a crack. Care should be taken to select an epoxy color (amber, white, or gray) that most closely matches the color of the concrete. Toners can be added to the epoxy mixture to more closely match color surfaces for cracks in the exposed face of the architectural concrete. When mixing the low-viscosity epoxy resin, the epoxy hardener, and color toner, do not shake or mix too vigorously, as this can infuse air into the epoxy, which would result in the formation of undesirable voids in the hardened epoxy. Cracks wider than 0.25 in. (6 mm) should be repaired with a gel-type resin system incorporating a mineral filler or a long pot-life material. Some cracks in precast products extending downward from nearly horizontal surfaces may be filled by gravity flow. The minimum width of a crack that can be filled by gravity is a function of the viscosity of the material. If a spalled piece of concrete is available and surfaces still mate, the easiest repair is to simply glue the piece back in place using non-sag epoxy or bonding agents. Broken surfaces on both the original surface and spalled piece should be painted with the epoxy adhesive. Enough epoxy should be applied to the surface that some squeezes out of the joint when mated pieces are bound together. An epoxy with a thick enough consistency should be selected so it does not sag or run on a vertical surface. Self-leveling formulations should not be used. In some cases, it may be better to secure the repair by inserting pins into epoxy-filled holes drilled in the loose piece and the original surface.

30.9.4 Cleaning

Dirt, mortar, plastic, grout, fireproofing, or debris from concrete placement should not be permitted to remain on the concrete and should be brushed or washed off immediately with clean water. Final cleaning should be performed after caulking is completed and no earlier than 3 days after any repairs have been completed. If at all possible, concrete cleaning should be done when the temperature and humidity allow rapid drying. Slow drying increases the possibility of recurring efflorescence and discoloration. Before cleaning, a small (at least 1 yd², or 0.8 m²) inconspicuous area should be cleaned and checked to be certain there is no adverse effect on the concrete surface finish or adjacent materials. The effectiveness of the method should not be judged until the surface has dried for at least a week. Materials such as glass, metal, wood, stone, or concrete adjacent to the area to be cleaned should be adequately protected, as they can be damaged by contact with some stain removers or by physical cleaning methods. A strip-off plastic that is sprayed on can be used to protect glass and aluminum frames. The following is a suggested order for testing appropriate procedures for the removal of dirt, stains, and efflorescence (beginning with the least damaging):

- Dry scrubbing with a stiff fiber (nylon) brush is particularly effective if the surface is brushed shortly after the appearance of efflorescence.
- Abrasive blasting with industrial baking soda will remove efflorescence without otherwise affecting the concrete surface. Water must not be used to remove any residue on the surface, as salts will

be dissolved and carried into the concrete, causing additional efflorescence. Residues should be blown, vacuumed, or brushed from the surface.

- Wet scrubbing may also be effective in removing efflorescence. This procedure involves wetting the surface with water, vigorously scrubbing the finish with a stiff fiber brush, and thoroughly rinsing the surface with clean water. Low-pressure water spraying (water misting), high-pressure water jet sprayers, and steam cleaning are alternative methods of wet scrubbing.
- Chemical cleaning compounds such as detergents, muriatic or phosphoric acid, or other chemical cleaners should be in accordance with the manufacturer's recommendations. If possible, a technical representative of the product manufacturer should be present for the initial test application to ensure it is properly used. Areas to be chemically cleaned should be thoroughly saturated with clean water prior to application of the cleaning material to prevent the chemicals from being absorbed deeply into the surface of the concrete. Surfaces should also be thoroughly rinsed with clean water after application so no traces of acid remain in the surface layers of the concrete. Cleaning solutions should not be allowed to dry on the concrete finish. Residual salts can flake or spall the surface or leave difficult stains. Misapplication of hydrochloric acid can lead to corrosion of embedded metals with shallow cover. Care should be taken to use dilute solutions of acid to prevent surface etching that may reveal the aggregate and slightly change the surface color and texture. The entire unit should be treated to avoid a mottled effect. Any of several diluted solutions of acids are effective ways to remove efflorescence:

One part hydrochloric (muriatic) acid in 9 to 19 parts water

One part phosphoric acid in 9 parts water

One part phosphoric acid plus 1 part acetic acid in 19 parts water

One part acetic acid (vinegar) in 5 parts water

Hydrochloric (muriatic) acid may leave a yellow stain on white concrete; therefore, phosphoric or acetic acid should be used to clean white concrete. Workers using cleaning compounds or acid solutions should be thoroughly trained in their use. The use of proper protective wear should be strictly enforced. Rubber gloves, glasses, and other protective clothing must be worn by workmen using acid solutions or strong detergents. Materials used in chemical cleaning can be highly corrosive and are frequently toxic. All precautions on labels should be observed because these cleaning agents can affect eyes, skin, and breathing. Materials that can produce noxious or flammable fumes should not be used in confined spaces unless adequate ventilation can be provided.

- Dry or wet abrasive blasting, using sand, ferrous aluminum silicate, or other abrasives, may be considered if this method was originally used in exposing the surface of the unit. An experienced subcontractor should be engaged for sandblasting.
- Stone-veneer-faced precast concrete units should be cleaned with stiff fiber or stainless-steel or bronze wire brushes, a mild soap powder or detergent, and clean water using high pressure, if necessary. No acid or other strong chemicals that might damage or stain the veneer should be used. Information should be obtained from stone suppliers on methods for cleaning oil, rust, and dirt stains on the stone.
- Mortar stains may be removed from brick panels by thoroughly wetting the panel and scrubbing with a stiff fiber brush and a masonry-cleaning solution. A prepared cleaning compound is recommended; however, on red brick, a weak solution of muriatic acid and water (not to exceed a 10% muriatic acid solution) may be used. Acid should be flushed off the panel with large amounts of clean water within 5 to 10 minutes of application. Buff, gray, or brown brick should be cleaned in accordance with the brick manufacturer's recommendations, using proprietary cleaners rather than acid to prevent green or yellow vanadium stains and brown manganese stains. Following the application of the cleaning solution, the panel should be rinsed thoroughly with clean water. High-pressure-water cleaning techniques, with a 1000 to 2000 psi (6.9 to 13.8 MPa) washer, may also be used to remove mortar stains. Unglazed tile or terra cotta surfaces should be cleaned with a 5% solution of sulfamic acid for gray or white joints, and a more dilute (2%) solution should be

used for colored joints. The surface should be thoroughly rinsed with clean water both before and after cleaning. Glazed tile manufacturers generally do not recommend the use of acid for cleaning purposes.

For information on removing specific stains from concrete, refer to *Removing Stains and Cleaning Concrete Surfaces* (PCI, 1988).

30.10 Acceptability of Appearance

At the time the visual mock-ups or initial precast production units are approved, the acceptable range in color, texture, and uniformity should be determined. If the procedures determined by the approved mock-up were continued throughout the project, final acceptance should not be a problem. Due to the inevitable nonuniformity of construction practices, some repairs will normally be required. Their final acceptability will depend on the blending capability and skill of the contractor's or precast manufacturer's restoration personnel. The final product is exposed to view, and faulty work anywhere in the construction process can be easily seen. Acceptance lies with the value judgment of the owner, architect, and consultant. For that reason, periodic review during construction and partial acceptance creates good will and confidence for all concerned. Uniformity of texture, intensity of color, and contrast range will determine whether an architectural concrete surface is acceptable. Acceptability will vary with the characteristics of the architecture and the average viewing distance. Finish texture, color, contrast, aggregate size, and shape all affect appearance. To establish a basic criteria for both architectural cast-in-place and precast concrete, a definitive rule for acceptability is as follows:

The finish face surface shall have no obvious imperfections other than minimal color and texture variations from the approved samples or evidence of repairs when viewed in good typical daylight illuminated with the unaided naked eye at a 20-ft (6-m) viewing distance. Appearance of the surface shall not be evaluated when sunlight is illuminating the surface from an extreme angle, as this tends to accentuate minor surface irregularities.

After final acceptance, the inspector's records should be completed and filed. If later additions are made or adjoining buildings constructed, these records will be necessary for construction.

30.11 Innovations

Today, more and more building contracts are negotiated or have a limited bid list. This will accelerate in the future with significant increases in value engineering. This incentive increases the team members' willingness to offer, approve, and implement ideas quickly. Project control systems will continue to be streamlined and productivity improved as more common systematic problems of information flow are corrected. Involvement of subcontractors and suppliers as equal partners will improve the flow of ideas and total job performance. We forecast that the use of architectural facades in combination with interior structural concrete will compete with other building systems. New materials or expanded uses include superplasticizers and 15,000-psi concrete. Improved concrete pumps are able to move concrete mixes with a high aggregate content. Tower cranes will be able to handle heavier loads at a greater reach. Fiberglass and steel forms designed to handle external form vibrators and full liquid head concrete have already begun to be used. Specialty vibrators are currently used to meet specific job performance requirements. Improved sealers, sealants, and specialty coatings are already available. Architectural precast concrete is combining textures, colors, and embedded materials such as clay products or natural stone. The industry is constantly striving to develop improved methods of production, better handling and erection, and new finishing techniques and ways of combining materials. The ability to customize the color, form, and texture of concrete allows limitless design possibilities.

30.12 Defining Terms

Abrasive blasting—A process in which sand or other materials are used to texture the surface of hardened concrete. The degree of blasting may vary from a light cleaning operation to one that exposes aggregate to a depth of 3/4 in. (19 mm) or more.

Admixture—A material other than water, aggregates, or cement used as an ingredient in concrete, mortar, or grout to impart special characteristics.

Aggregate—Granular material, such as sand, gravel, and crushed stone, used with a cementing medium to form a hydraulic-cement concrete or mortar.

Architectural concrete—Any concrete with one or more surfaces to be permanently exposed to view and where the appearance of these surfaces is important from an architectural standpoint; a precast product with a specified standard of uniform appearance, surface details, color, and texture.

Backup mix—The concrete mix cast into the mold after the face mix has been placed and consolidated.

Bond breaker—A substance placed on a material to prevent it from bonding to the concrete or between a face material such as natural stone and the concrete backup.

Bonding agent—A substance used to increase the bond between an existing piece of concrete and a subsequent application of concrete such as a patch.

Bug holes—Small holes on formed concrete surfaces formed by air or water bubbles, sometimes referred to as *blow holes*.

Bushhammering—A process in which pneumatic or hand hammers are used to remove mortar and fracture aggregate at the surface of hardened concrete to produce an attractive varicolored and textured surface.

Coarse aggregate—Aggregate predominately retained on the U.S. Standard No. 4 (4.75-mm) sieve or that portion of an aggregate retained on the No. 4 (4.75-mm) sieve.

Crazing—A network of visible, fine hairline cracks in random directions breaking the exposed face of a panel into areas from 1/4 to 3 in. (6 to 75 mm) across.

Exposed-aggregate concrete—Concrete manufactured so the aggregate on the face is left protruding.

Exposed concrete—Any concrete with one or more surfaces to be permanently and regularly revealed to public view but where the appearance of the concrete surface is not important from an architectural standpoint.

Face mix—The concrete at the exposed face of a concrete unit used for specific appearance purposes.

Fine aggregate—Aggregate passing the 3/8-in. (9.5-mm) sieve and almost entirely passing the No. 4 (4.75-mm) sieve and predominately retained on the No. 200 (75- μ m) sieve, or that portion of an aggregate passing the No. 4 (4.75-mm) sieve and predominately retained on the No. 200 (75- μ m) sieve.

Form-release agent—A substance applied to the mold for the purpose of preventing bond between the mold and the concrete cast in it.

Gap-graded concrete—A mix with one or a range of normal aggregate sizes eliminated or with a heavier concentration of certain aggregate sizes over and above standard gradation limits; used to obtain a specific exposed-aggregate finish.

Matrix—The portion of the concrete mix containing only the cement and fine aggregates (sand).

Quality—The appearance, strength, and durability that are appropriate for a specific product, its particular application, and its expected performance requirements; the totality of features and characteristics of a product that bear on its ability to satisfy stated or implied needs.

Quality assurance (QA)—All those planned or systematic actions necessary to ensure that the final product or service will satisfy given requirements for quality and perform intended function.

Quality control (QC)—Those actions related to the physical characteristics of the materials, processes, and services that provide a means to measure and control the characteristics to predetermined quantitative criteria.

31.1 Introduction

Life safety and property protection are critical functions of all structures, particularly as they relate to fire safety. Further, the functionality of these structures is influenced by their design, construction, and maintenance. Key elements of the design, which have an impact on both the life safety and property protection functions, include the principles of balanced design that incorporate compartmentation to limit the spread of fire, early detection to alert occupants when a fire occurs, and automatic suppression to control a fire until it can be extinguished. Concrete and masonry materials are inherently fire resistant, noncombustible, and durable and maintain structural integrity under fire conditions. These features are used in the design of compartments to contain fire and in the design of structural elements to maintain

** Director of Engineering, National Concrete Masonry Association, Herndon, Virginia; active member of several professional societies and codes and standards development committees, including ACI 530/ASCE 5/TMS 402, *Building Code Requirements for Masonry Structures*, and ACI 530.1/ASCE 6/TMS 602, *Specification for Masonry Structures*.

structural integrity during a fire. The durability and permanence of concrete and masonry can be relied on for life safety and property protection throughout the life of the structure, with minimal investment in maintenance or repair. This chapter presents criteria for the design of concrete and masonry elements to ensure both property protection and life safety functions during fire conditions.

31.1.1 Balanced Design for Fire Safety and Property Protection

Fire safety requires an awareness and understanding of the hazards so both the potential for fire occurrence and the threat to life and property during a fire are minimized. Death and injury from fire are caused by asphyxiation from toxic smoke and fumes, burns from direct exposure to the fire, heart attacks caused by stress and exertion, and impact due to structural collapse, explosions, and falls. Life safety and property protection are influenced by the design of the building, its fire-protection features, and the quality of construction materials, building contents, and maintenance. Balanced design relies on three complementary systems to reduce the risk of death and the threat to property due to fire:

- A detection system to warn occupants of the fire
- A containment system to limit the extent of the fire
- An automatic suppression system to control the fire until it can be extinguished

Each of these essential systems contributes to lowering the risk of death and injury from fire as well as to protecting property. The three balanced-design components complement each other by providing fire protection features that are not provided by the other components. Some features of each balanced-design component are intended to be redundant so if one system is breached or fails to perform, then the other components continue to provide safety. Although not a tangible element in fire protection, a strong education and training program should be an integral part of any good fire-protection plan in addition to the physical components of a balanced-design system.

31.1.1.1 Automatic Detection

Accurate early warning is the first line of defense against slow smoldering fires with low heat release rates that do not activate sprinkler heads. Detectors that respond to light smoke are important from a life-safety standpoint because they alert occupants near the origin of the fire to evacuate. Other detection or alarm systems may be used to notify the fire department, thus decreasing response time, expediting rescue operations, and limiting the resulting fire spread and property damage. Detectors wired to a central alarm and installed in corridors and common areas notify all building occupants, allow timely and orderly evacuation, and decrease the potential for injury and death. The most common detector installed is the smoke-sensing fire detector. Ideally, detectors should be wired into a continuous power supply and be provided with a battery backup in the event of a power failure. Their location is determined by judgment and in accordance with the requirements of the general building code. Each dwelling unit in residential construction should be equipped with detectors in all sleeping rooms, in areas adjacent to all sleeping rooms, and on each level of the building, including the basement. The amount of air movement, obstructions within the space, number of stories, and other factors will guide the proper selection of detector locations. The performance of detectors is vulnerable to many unpredictable malfunctions, among which are those due to acts of sabotage, lack of maintenance due to human error and neglect, and faulty power supply. Young children, the incapacitated, or the elderly may not be able to respond to alarms. All smoke detectors require regularly scheduled maintenance and, in some cases, periodic replacement.

31.1.1.2 Automatic Suppression

The function of automatic sprinkler systems is to control a fire at the point of origin. Although not designed to extinguish a fire, residential sprinklers have been shown to be reliable and effective in controlling a fire in the room of origin until it can be extinguished. Automatic sprinklers reduce the likelihood of *flashover*, the near instantaneous ignition of volatile gasses within a confined space which can be a particularly hazardous event. Suppression of a fire allows access to the building to permit rescue

and fire suppression efforts to proceed. Through the years, sprinklers have been credited with preventing hundreds, possibly thousands, of injuries and deaths.

The National Fire Protection Association (NFPA) maintains minimum standards for the design and installation of sprinkler systems. Sprinkler systems for general application are covered by NFPA 13, *Standard for the Installation of Sprinkler Systems* (NFPA, 2007a), whereas NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height* (NFPA, 2007b), specifically address residential applications. Ideally, when the interior construction or building contents contain a large amount of combustibles, sprinkler systems should meet the requirements of NFPA 13, regardless of height, to ensure protection in attics, closets, and other concealed spaces built with combustible materials and to provide additional suppression in all areas due to the higher fuel loadings.

The NFPA standards cover the design, installation, testing, and maintenance of sprinkler systems. Obviously, to be effective, automatic sprinklers require an adequate water supply and piping system to deliver sufficient water to the sprinkler head. Sprinkler head requirements ensure proper water coverage based on the room dimensions, area to be covered, and fuel loading. The standards also list exceptions for specific spaces that are not required to be sprinklered. When installation is complete, the standards require inspection and acceptance of the piping valves, pumps, and tanks of the system. Testing also includes verification of adequate water flow to the sprinkler heads. Finally, after the sprinkler system is in use, it must be maintained; however, specific maintenance requirements and frequency of maintenance are not specified by the standards.

Performance of automatic sprinklers can be vulnerable to system failures due to inadequate maintenance and inspection or inadequate water supply. Sprinklers are not intended to control electrical and mechanical equipment fires or fires of external origin, such as fires from adjacent buildings and brush fires. Fires in concealed spaces, including some attics, closets, flues, shafts, ducts, and other spaces where sprinkler heads are not required to be installed, can compromise life safety due to the spread of toxic fumes and smoke. An inadequate water supply can result from low pressure in the municipal water system, broken pipes due to earthquakes or excavation equipment, explosions, freezing temperatures, closed valves due to human error, arson or vandalism, corrosion of valves, pump failure due to electrical outage, and lack of system maintenance.

31.1.1.3 Compartmentation

Compartmentation limits the extent of fire by dividing a building into fire compartments enclosed by fire walls or fire separation wall assemblies and by fire-rated floors and ceilings. Compartments also minimize the spread of toxic fumes and smoke to adjacent areas of a building. Conflagrations beyond the fire compartment are prevented by limiting the total fuel load contributing to the fire. Compartmentation provides safe areas of refuge for handicapped, young, elderly, incapacitated, and other occupants who may not be capable of unassisted evacuation. Compartmentation also provides safe areas of refuge for extended periods when evacuation is precluded due to smoke-filled exit ways or blocked exits. Compartmented construction provides protection for fire and rescue operations. Highly hazardous areas, such as mechanical, electrical, or storage rooms, can be isolated from other occupied areas of a building by fire walls. Fire separation walls and floor and ceiling assemblies between dwelling units in multifamily housing afford protection from fires caused by the carelessness of other occupants. Refuge areas within a building provide protection for occupants by allowing fire fighters to concentrate on extinguishing the fire rather than on rescue efforts.

Compartmentation serves to contain a fire until it can be brought under control by firefighters. Each concrete or masonry element forming the boundary of a compartment should have a fire-resistance rating as defined by the general building code and should be capable of preserving the structural integrity of the building throughout the duration of the fire. In multifamily housing, each dwelling unit should form a separate compartment. In addition, interior exit ways, as well as storage, electrical, and mechanical rooms, should be separate compartments. Exterior walls should be fire rated to form a barrier to the penetration of exterior fires and to contain interior fires.

TABLE 31.1 Fire-Safety Functions of Balanced Design

Function	Automatic Detection	Compartmentation	Automatic Suppression
Controls fire/limits fire growth	○	●	●
Provides smoke, toxic-fume barrier	○	●	○
Provides fire barrier	○	●	○
Limits generation of smoke/toxic fumes	○	■	●
Allows safe egress	■	●	■
Provides refuge	○	●	○
Assists fire-fighting efforts	○	■	■
Reduces response time	●	○	○
Difficult to vandalize or arson	○	●	○
Performance requires little maintenance	○	●	○
<i>Property protection functions and costs of balanced design component</i>			
Limits the extent of contents damage	■	■	■
Limits the extent of structure damage	■	●	■
Low installation costs	●	■	○
Low maintenance costs	■	●	○
Limits repair time due to fire damage	■	●	●

Note: ●, Considered to be effective; ■, considered to be partially effective; ○, considered to be ineffective or only slightly effective.

The value of compartmentation may be reduced when joints between floors and walls, typically exterior curtain walls, or between walls and ceilings are not properly fire-stopped. As such, openings through compartment boundaries should be protected to prevent the migration of smoke and fire. Damage caused by equipment, abuse, or the installation of utilities that are not properly sealed can allow the passage of smoke and gas. Unsealed openings around penetrations can also allow the spread of smoke. Self-closing mechanisms on doors in compartment walls may fail if not maintained or if blocked open.

31.1.1.4 Property Protection

The initial cost of providing fire safety can be significant; however, balanced design offers advantages that offset costs. The higher level of protection for both the structure and its contents limits the potential loss due to fire. Immediate and long-term savings will be reflected in lower insurance rates for both the building and its furnishings. Balanced design limits both fire and smoke damage to the contents of the building to the compartment of fire origin. Noncombustible compartment boundaries limit damage to the structure itself and reduce repair time following a fire. Repair is generally nonstructural but may include the replacement of doors and windows; electrical outlets, switches, and wiring; heating ducts and registers; and floor, wall, and ceiling coverings.

31.1.1.5 State of the Art in Designing for Fire Safety

Fire-protection engineering is as much an art as it is a science. The number of unknowns and potential fire propagation scenarios are numerous. Fire protection is therefore generally based more on risk assessment than on precise calculation. Currently, building code prescriptive criteria, along with an understanding of the science of fire protection, guide the designer in addressing fire safety (ACI Committee 216, 1997, 2001; ICC, 2006; NIST, 1993). Some of the more significant fire safety issues requiring consideration are listed in Table 31.1, along with a relative ranking of the effectiveness of each component in contributing to balanced design. As shown by the table, more than one component may be considered effective in mitigating a particular hazard. Because none of the components is fail safe, overlapping functions are required to provide a necessary level of safety. In addition, some functions listed in the table are addressed by only one component of balanced design. There is general agreement among the fire safety and regulatory communities that computer modeling will serve to continue improving fire safety in the built environment. Widespread access to complex analytical models and computing equipment is giving fire safety engineers new and ever-evolving tools to bolster fire safety requirements in buildings.

31.1.2 Design, Construction, and Material Requirements

The fire-resistance ratings of concrete and masonry assemblies assume that the design and construction of these elements comply with the provisions of the *Building Code Requirements for Masonry Structures* (ACI Committee 530, 2005) and the *Building Code Requirements for Structural Concrete* (ACI Committee 318, 2005) for masonry and concrete elements, respectively. These codes stipulate material requirements by reference to ASTM standards and establish quality assurance provisions for the construction of these elements.

31.2 Fire-Resistance Ratings

Two major factors have to be considered in ratings: fire endurance and fire resistance. The definitions of these two terms, per ACI 216, are as follows:

- *Fire endurance*—A measure of the elapsed time during which a material or assembly continues to exhibit fire resistance under specified conditions of test and performance; as applied to elements of buildings, it shall be measured by the methods and to the criteria defined in ASTM E 119.
- *Fire resistance*—The property of a material or assembly to withstand fire or to give protection from it; as applied to elements of buildings, it is characterized by the ability to confine a fire or to continue to perform a given structural function, or both.

Building codes establish the minimum level of required fire resistance for specific elements within the structure based on the type of occupancy of the building, the function of the element, the importance of the structure, its contents, and other fire-protection considerations. When the required fire-resistance rating of a concrete or masonry element has been established, this chapter can assist the designer in meeting that requirement.

The fire-resistance rating criteria presented here are based on the provisions of the ACI 216.1/TMS 0216, *Standard Method for Determining Fire Resistance of Concrete and Masonry Construction Assemblies* (ACI Committee 216, 1997). This consensus standard, which is referenced by model building codes, is based on current practice in determining the fire ratings of concrete and masonry elements. The standard covers two methods of determining the fire-resistance rating of an element. The most common method for determining the fire-resistance rating is based on a calculation procedure that has established a correlation between the physical properties of the concrete or masonry member and the measured fire endurance as determined through testing in accordance with ASTM E 119, *Standard Test Methods for Fire Tests of Building Construction and Materials* (ASTM, 2005b). The second method allows for direct measurement of the fire resistance of an element or assembly through testing in accordance with ASTM E 119. A third option, which is not explicitly covered by existing codes and standards, is to establish the fire-resistance rating through a listing service, such as Underwriters Laboratory.

Fire testing of wall assemblies in accordance with ASTM E 119 defines four performance criteria that must be met:

- Resistance to the transmission of heat through the wall assembly
- Resistance to the passage of hot gases or flame through the assembly sufficient to ignite cotton waste on the non-exposed side
- Loss of load-carrying capacity of load-bearing walls
- Resistance to the impact, erosion, and cooling effects of a hose stream on the assembly after exposure to fire

The fire-resistance ratings of concrete and masonry elements are typically governed by the transmission of heat through the assembly, which is measured by temperature rise on the non-fire-exposed side of the wall. This consistent mode of failure allows for a standardized calculation procedure to be derived as described below. Conversely, the fire-resistance rating of other construction assemblies, particularly those consisting of combustible materials, is often governed by one of the other performance criteria.

* Reinforcement index for concrete beams reinforced with mild reinforcement: $\omega = A_s f_s / b d f_c$

** Reinforcement index for concrete beams reinforced with prestressing steel: $\omega_p = A_{sp} f_{sp} / b d f_c$

FIGURE 31.1 Fire resistance of concrete slabs. (From ACI Committee 216, *Guide for Determining the Fire Endurance of Concrete Elements*, ACI 216R, American Concrete Institute, Farmington Hills, MI, 2001.)

31.2.1 Heat Transmission in Slabs

The structural fire endurance of simply supported concrete slabs as affected by the constituent materials can be interpolated from Figure 31.1 by an effective concrete cover parameter (u) as a function of the moment ratio M/M_n , where M is the design moment and M_n is the nominal moment strength. In the usual case of continuous slabs and beams, a shift in the moment distribution develops, thereby increasing the stresses in the negative reinforcement resulting from the increase in the bending moments at the supports. During a fire, however, the negative reinforcement remains cooler than the positive reinforcement as it is often farther from the source of the fire. This in turn allows for an increase in the negative moment that can be accommodated (ACI Committee 216, 1997). Although the moment redistribution that results can be sufficient to result in yielding of the negative reinforcement, the resulting decrease in the positive moment in effect permits the beam or slab span to endure higher temperatures. The negative moment reinforcing bars must be long enough to accommodate the complete redistributed moments and the change of the location of the inflection points. At least 20% of the maximum negative moment reinforcement must be extended throughout the span (CEB/FIP, 1990). The fire-resistance rating of concrete slabs can also be increased through the use of undercoating, as described in ACI 216.1/TMS 0216 (ACI Committee 216, 1997).

31.2.2 Fire-Resistance Ratings of Single-Wythe Masonry Walls

The fire-resistance rating of masonry walls, including single-wythe walls, multi-wythe walls, and walls with finish treatments, is based on the following criteria, which includes the effect of grouting and the effect of filling the cores of hollow units with recognized loose fill materials.

TABLE 31.2 Fire-Resistance Rating Period of Concrete Masonry Assemblies

Aggregate Type in the Concrete Masonry Unit ^b	Minimum Required Equivalent Thickness (in.) for Fire-Resistance Rating ^a						
	4 hr	3 hr	2 hr	1.5 hr	1 hr	0.75 hr	0.5 hr
Calcareous or siliceous gravel	6.2	5.3	4.2	3.6	2.8	2.4	2.0
Limestone, cinders, or slag	5.9	5.0	4.0	3.4	2.7	2.3	1.9
Expanded clay, shale, or slate	5.1	4.4	3.6	3.3	2.6	2.2	1.8
Expanded slag or pumice	4.7	4.0	3.2	2.7	2.1	1.9	1.5

^a Fire-resistance ratings between the hourly fire-resistance rating periods listed are determined by linear interpolation based on the equivalent thickness value of the concrete masonry wall assembly.

^b Minimum required equivalent thickness corresponding to the hourly fire-resistance rating for units made with a combination of aggregates is determined by linear interpolation based on the percent by volume of each aggregate used in the manufacturing of the unit.

TABLE 31.3 Fire-Resistance Rating of Clay Masonry Assemblies

Material Type	Minimum Required Equivalent Thickness (in.) for Fire-Resistance Rating ^{a,b}			
	1 hr	2 hr	3 hr	4 hr
Solid brick of clay or shale ^c	2.7	3.8	4.9	6.0
Hollow brick or tile of clay or shale, unfilled	2.3	3.4	4.3	5.0
Hollow brick or tile of clay or shale, grouted or filled with perlite, vermiculite, or expanded shale aggregate	3.0	4.4	5.5	6.6

^a Fire-resistance ratings between the hourly fire-resistance rating periods listed should be determined by linear interpolation.

^b Where combustible members are framed into the wall, the thickness of solid material between the end of each member and the opposite face of the wall or between members set in from opposite sides should not be less than 93% of the thickness shown.

^c For units in which the net cross-sectional area of cored brick in any plane parallel to the surface containing the cores should be at least 75% of the gross cross-sectional area measured in the same plane.

31.2.2.1 Single-Wythe Concrete Masonry Walls

The calculated fire-resistance rating of single-wythe concrete masonry assemblies is determined in accordance with Table 31.2. These calculated fire-resistance ratings are derived from the requirements of ACI 216.1/TMS 0216. The equivalent thickness (T_{ea}) of concrete masonry assemblies is based on the equivalent thickness of the masonry unit (T_e) plus the equivalent thickness of any recognized finish materials (T_{ef}) as follows:

$$T_{ea} = T_e + T_{ef} \quad (31.1)$$

The equivalent thickness (T_e) of a concrete masonry unit is the net volume of the unit divided by the face area of the unit (length times height). The equivalent thickness (T_e) of solid grouted masonry walls is the actual thickness of the unit. The equivalent thickness (T_e) of hollow masonry unit walls that are completely filled with loose fill is the actual thickness of the unit when the loose fill materials are sand, pea gravel, crushed stone, or slag that meet ASTM C 33 (ASTM, 2003) requirements; pumice, scoria, expanded shale, expanded clay, expanded slate, expanded slag, expanded fly ash, or cinders that comply with ASTM C 331 (ASTM, 2005a); or perlite or vermiculite meeting the requirements of ASTM C 549 and ASTM C 516, respectively (ASTM, 2002, 2006).

31.2.2.2 Single-Wythe Clay Masonry Walls

The calculated fire-resistance rating of single-wythe clay masonry assemblies is determined in accordance with Table 31.3. The equivalent thickness (T_e) of clay masonry assemblies is determined as follows:

$$T_e = V_n / LH \quad (31.2)$$

As with concrete masonry assemblies, when solid grouted or when completely filled with approved loose fill materials, the equivalent thickness (T_e) of a clay masonry assembly is the actual thickness of the unit.

TABLE 31.4 Fire-Resistance Rating of Single-Layer Concrete Walls, Floors, and Roofs

Aggregate Type	Minimum Equivalent Thickness (in.) for Fire-Resistance Rating				
	1 hr	1.5 hr	2 hr	3 hr	4 hr
Siliceous	3.5	4.3	5.0	6.2	7.0
Carbonate	3.2	4.0	4.6	5.7	6.6
Semi-lightweight	2.7	3.3	3.8	4.6	5.4
Lightweight	2.5	3.1	3.6	4.4	5.1

31.2.3 Single-Layer Concrete Walls, Floors, and Roofs

The fire-resistance rating of plain and reinforced concrete walls, floors, and roofs that are a single layer in thickness are determined in accordance with Table 31.4 and are based on the equivalent thickness of the element. The equivalent thickness of solid concrete elements with flat surfaces is the actual thickness of the element. The equivalent thickness of hollow-core panels with a constant cross-section throughout their length is determined by dividing the net cross-sectional area by the panel width. The equivalent thickness of elements in which all of the core spaces are filled with grout or loose fill material, such as perlite, vermiculite, sand or expanded clay, shale, slag, or slate, should be the same as that of a solid wall or slab of the same type of concrete. The equivalent thickness for flanged elements in which the flanges taper is determined at the location of the lesser distance of two times the minimum thickness, or 6 in. from the point of the minimum thickness of the flange. The equivalent thickness of elements with ribbed or undulating surfaces is determined as follows:

- Where the center-to-center spacing of ribs or undulations is not less than four times the minimum thickness, the equivalent thickness is the minimum thickness of the panel.
- Where the spacing of ribs or undulations is equal to or less than two times the minimum thickness, calculate the equivalent thickness by dividing the net cross-sectional area by the panel width. The maximum thickness used to calculate the net cross-sectional area should not exceed two times the minimum thickness.
- Where the spacing of ribs or undulations exceeds two times the minimum thickness, but is less than four times the minimum thickness, calculate the equivalent thickness as follows:

$$\text{Equivalent thickness} = t + \left[\left(4t / s \right) - 1 \right] (t_e - t) \quad (31.3)$$

where:

- s = spacing of ribs or undulations (in.).
- t = minimum thickness (in.).
- t_e = equivalent thickness calculated in accordance with Equation 31.2.

31.2.4 Multiple-Layer Walls, Floors, and Roofs

ACI 216.1/TMS 0216 (ACI Committee 216, 1997) offers several alternatives to calculating the fire-resistance rating of multi-wythe and multi-layer walls, floors, and roofs using graphical, analytical, and numerical solutions. Each alternative considers various possible combinations of normal weight, semi-lightweight, and lightweight concretes; sandwich panels and insulation systems; and the use of concrete and clay masonry assemblies as part of a veneer or multi-wythe system. In addition to the material properties, the resulting fire-resistance rating is influenced by the use of finish materials, exposure conditions, and reinforcement cover distances. The user is referred to ACI 216.1/TMS 0216 for additional information on determination of the fire-resistance properties of multiple-layer concrete and masonry systems.

FIGURE 31.2 Two-hour control joint.

31.3 Fire Protection of Joints

31.3.1 Masonry Elements

Expansion or contraction joints in fire-rated concrete masonry wall assemblies and in clay brick wall assemblies are shown in Figure 31.2, Figure 31.3, and Figure 31.4. Figure 31.2 illustrates a standard control joint detail for a 2-hour fire-resistance rating, and Figure 32.3 and Figure 32.4 offer alternatives for 4-hour fire-resistance ratings.

31.3.2 Precast Concrete Wall Panels and Slabs

In wall panels where openings are not permitted or where it is required that openings be protected, joints must be insulated. Joints between panels that are not insulated are considered unprotected openings. Where the percentage of unprotected openings is limited in exterior walls, the area of uninsulated joints is added to the area of other unprotected openings to determine the total area of unprotected openings. Protected joints between precast concrete wall panels are filled with ceramic fiber blankets, the minimum thickness of which is calculated in accordance with ACI 216.1/TMS 0216 (ACI Committee 216, 1997). Other approved joint treatment systems that maintain the required fire-resistance rating are also used. Alternatively, joints between adjacent precast concrete slabs may be ignored when calculating the equivalent slab thickness, provided that a concrete topping not less than 1 in. thick is used. Where a concrete topping is not used, joints should be grouted to a depth of at least one third the slab thickness at the joint, but not less than 1 in., or the fire-resistance rating of the floor or roof must be maintained by other approved methods.

FIGURE 31.3 Four-hour control joint.

FIGURE 31.4 Four-hour control joint.

TABLE 31.5 Multiplying Factors for Finishes on the Non-Fire-Exposed Side of Concrete Slabs and Concrete and Masonry Walls

Type of Finish Applied to Slab or Wall	Type of Material Used in Slab or Wall		
	Siliceous or Carbonate Aggregate Concrete or Concrete Masonry Unit; Solid Clay Brick Masonry	Semi-Lightweight Concrete; Hollow Clay Brick; Clay Tile	Lightweight Concrete; Concrete Masonry Units of Expanded Shale, Expanded Clay, Expanded Slag, or Pumice Less Than 20% Sand
Portland cement–sand plaster ^a or terrazzo	1.00	0.75	0.75
Gypsum–sand plaster	1.25	1.00	1.00
Gypsum–vermiculite or perlite plaster	1.75	1.50	1.25
Gypsum wallboard	3.00	2.25	2.25

^a For Portland cement–sand plaster 5/8 in. or less in thickness and applied directly to concrete or masonry on the non-fire-exposed side of the wall, the multiplying factor is 1.0.

31.4 Finish Treatments

Finish treatments on concrete and masonry elements include gypsum drywall, terrazzo, or plaster. These treatments increase the fire-resistance rating of the element by delaying the temperature rise within or through the element when exposed to fire. The effect of this increase is based on whether the finish is applied to the side of the element being exposed to the fire or to the side that is not exposed to the fire. The fire-resistance rating of elements that may be exposed to fire from either side is determined based on the lower rating determined from assuming that the fire exposure is from one side or the other. The fire-resistance rating of the element including the effect of finish treatments is limited to twice the fire rating of the element excluding the effect of finish treatments. Further, the effect of finish treatments from the non-fire-exposed side of the wall is limited to one half the fire-resistance rating of the element excluding the effect of finish treatments. Finishes that are assumed to contribute to the total fire-resistance rating of an assembly must meet the minimum installation requirements as prescribed in ACI 216.1/TMS 0216.

Some finishes deteriorate more rapidly when exposed to fire than when installed on the non-exposed side of an assembly. For this reason, ACI 216.1/TMS 0216 requires two separate calculations assuming, first, that the fire exposure is on one side of the wall and then again assuming that the fire is on the other side of the wall. Table 31.5 applies to finishes on the non-fire-exposed side of the wall, while Table 31.6 applies to finishes on the fire-exposed side. The resulting fire rating of the wall assembly is the smaller of the two calculated ratings. Note that in some situations the fire is assumed to occur only on one side of the wall. For finishes on the non-fire-exposed side of the wall, the finish is converted to equivalent thickness of concrete or masonry by multiplying the thickness of the finish by the factor given in Table 31.5. This is then added to the base equivalent thickness per Equation 31.1. For finishes on the fire-exposed side of the wall, a time is assigned to the finish per Table 31.6, which is added to the fire-resistance rating determined for the base wall and non-fire-side finish. The additional times listed in Table 31.6 are essentially the length of time the various finishes will remain intact when directly exposed to fire.

31.5 Fire Resistance of Columns

31.5.1 Reinforced Masonry Columns

The fire-resistance rating of reinforced concrete and clay masonry columns is based on the least plan dimension of the column in accordance with the requirements of Table 31.7. The minimum cover for longitudinal reinforcement, measured from the outside surface of the reinforcement to the nearest outside surface of the masonry, is not permitted to be less than 2 in.

TABLE 31.6 Time Assigned to Finish Materials on Fire-Exposed Side of Concrete and Masonry Walls

Finish Description	Time (minutes)
<i>Gypsum wallboard</i>	
3/8-in.	10
1/2-in.	15
5/8-in.	20
Two 3/8-in. layers	25
One 3/8-in. layer and one 1/2-in. layer	35
Two 1/2-in. layers	40
<i>Type X gypsum wallboard</i>	
1/2-in.	25
5/8-in.	40
Direct applied Portland cement–sand plaster	— ^a
<i>Portland cement–sand plaster on metal lath</i>	
3/4-in.	20
7/8-in.	25
1-in.	30
<i>Gypsum–sand plaster on 3/8-in. gypsum lath</i>	
1/2-in.	35
5/8-in.	40
3/4-in.	50
<i>Gypsum–sand plaster on metal lath</i>	
3/4-in.	50
7/8-in.	60
1-in.	80

^a The fire-resistance rating of elements with Portland cement–sand plaster finish treatment is determined by adding the actual thickness of the plaster or 5/8 in., whichever is smaller, to the equivalent thickness of the element.

TABLE 31.7 Reinforced Masonry Columns

	Fire Resistance (hr)			
	1	2	3	4
Minimum column dimension (in.)	8	10	12	14

TABLE 31.8 Minimum Concrete Column Size

Aggregate Type	Minimum Column Dimension for Fire-Resistance Rating (in.)				
	1 hr	1.5 hr	2 hr	3 hr	4 hr
Carbonate	8	9	10	11	12
Siliceous	8	9	10	12	14
Semi-lightweight	8	8.5	9	10.5	12

31.5.2 Reinforced-Concrete Columns

The fire-resistance ratings of reinforced-concrete columns, both circular and rectangular, are determined in accordance with the requirements of Table 31.8. When a concrete column is exposed to fire on two parallel sides, additional requirements as prescribed in ACI 216.1/TMS 0216 (ACI Committee 216, 1997) must be met. The minimum thickness of concrete cover to the longitudinal reinforcement in concrete columns should not be less than 1 in. times the number of hours of required fire resistance, or 2 in., whichever is less.

31.6 Steel Columns Protected by Masonry

Because of its inherent fire-resistant properties, masonry is often used as a nonstructural fire-protection covering for structural steel members. The fire endurance of steel column protection is determined as the period of time for the average temperature of the steel to exceed 1000°F or for the temperature at any measured point to exceed 1200°F (ASTM, 2005b). These criteria depend on the thermal properties of the column cover and of the steel column. Accurate predictions of the fire endurance of protected steel columns are made possible by a numerical technique based on heat-flow analyses and research information on the thermal and rheological properties of masonry and steel at elevated temperatures (Lie and Harmathy, 1972). Using this technique, an empirical formula was developed to predict the fire endurance of masonry-protected steel columns in accordance with ACI 216.1/TMS 0216 (ACI Committee 216, 1997). The fire-resistance rating of structural steel columns protected by masonry is determined as follows:

$$R = 0.401(A_{st}/p_s)^{0.7} + \left[0.285(T_{ea}^{1.6}/k_{cm}^{0.2}) \right] \left[1.0 + 42.7 \left\{ (A_{st}/DT_{ea}) / (0.25p + T_{ea}) \right\}^{0.8} \right] \quad (31.4)$$

where:

R = fire-resistance rating of the protected column assembly (hr).

A_{st} = cross-sectional area of the structural steel column (in.²).

D = density of the masonry protection (lb/ft³).

p = inner perimeter of the masonry protection (in.).

p_s = heated perimeter of steel column (in.), per Equations 31.5, 31.6, or 31.7.

T_{ea} = equivalent thickness of the concrete masonry protection assembly (in.)

k = thermal conductivity of the masonry protection (BTU/hr·ft·°F).

For a W-section steel column, the heated perimeter (p_s) is determined as follows:

$$p_s = 2(b_f + d_{st}) + 2(b_f - t_w) \quad (31.5)$$

For a pipe-section steel column, the heated perimeter (p_s) is determined as follows:

$$p_s = \pi d_{st} \quad (31.6)$$

For a square-tube steel column, the heated perimeter (p_s) is determined as follows:

$$p_s = 4d_{st} \quad (31.7)$$

where:

b_f = width of flange (in.).

d_{st} = column depth (in.).

t_w = thickness of web of W-section (in.).

For use in Equation 31.4, the thermal conductivity of concrete masonry is:

$$k = 0.0417_e^{0.02D} \quad (31.8)$$

Likewise, the thermal conductivities of clay masonry are equal to:

$k = 1.25$ BTU/hr·ft·°F for a density of 120 lb/ft³.

$k = 2.25$ BTU/hr·ft·°F for a density of 130 lb/ft³.

Steel Column Fire Protection (NCMA, 2003) contains a comprehensive list of fire-resistance ratings for a wide variety of structural steel sections.

TABLE 31.9 Reinforced Masonry Lintels

Nominal Lintel Width (in.)	Minimum Longitudinal Reinforcement Cover for Fire-Resistance Rating (in.)			
	1 hr	2 hr	3 hr	4 hr
6	1.5	2	Not permitted	Not permitted
8	1.5	1.5	1.75	3
10 or more	1.5	1.5	1.5	1.75

31.7 Fire Resistance of Lintels

The fire-resistance rating of masonry lintels (beams spanning openings) is based on the nominal thickness of the lintel and the minimum provided cover for the longitudinal reinforcement as shown in Table 31.9. The cover is measured from the outside surface of the reinforcement to the nearest outside surface of masonry, which may consist of masonry units, grout, or mortar.

32.1 Fundamentals of Earthquake Ground Motion

32.1.1 Introduction

When transmitted through a structure, ground acceleration, velocity, and displacements (referred to as *ground motion*) are in most cases amplified. The amplified motion can produce forces and displacements that may exceed those the structure can sustain. Many factors influence ground motion and its amplification. An understanding of how these factors influence the response of structures and equipment is essential for a safe and economical design. Earthquake ground motion is usually measured by a strong-motion accelerograph that records the acceleration of the ground at a particular location. Record accelerograms, after they are corrected for instrument errors and adjusted for baseline, are integrated to obtain velocity and displacement-time histories. The maximum values of the ground motion (peak ground acceleration, peak ground velocity, and peak ground displacement) are of interest for seismic analysis and design. These parameters, however, do not by themselves describe the intensity of shaking that structures or equipment experience. Other factors, such as the earthquake magnitude, distance from fault or epicenter, duration of strong shaking, soil condition of the site, and frequency content of the motion, also influence the response of a structure. Some of these effects, such as the amplitude of motion, duration of strong shaking, frequency content, and local soil conditions, are best represented through the response spectrum (1.1 to 1.4), which describes the maximum response of a damped, single-degree-of-freedom oscillator to various frequencies or periods. The response spectra from a number of records are often averaged and smoothed to obtain design spectra, which also represent the amplification of ground motion at various frequencies or periods of the structure. This section discusses earthquake ground motion. The influence of earthquake parameters such as earthquake magnitude, duration of strong motion, soil condition, and epicentral distance on ground motion is presented and discussed.

32.1.2 Recorded Ground Motion

Ground motion during an earthquake is measured by a strong-motion accelerograph that records the acceleration of the ground at a particular location. Three orthogonal components of the motion, two in the horizontal direction and one in the vertical, are recorded by the instrument. The instruments may be located in a free field or mounted in structures. Accelerograms are generally recorded on photographic paper or film. The records are digitized for engineering applications, and during the digitization process errors associated with instruments and digitization are removed. The digitization, correction, and processing of accelerograms have been carried out by the Earthquake Engineering Research Laboratory of the California Institute of Technology in the past and are now carried out by the U.S. Geological Survey.

32.1.3 Characteristics of Earthquake Ground Motion

Characteristics of earthquake ground motion that are important in earthquake engineering applications include:

- Peak ground motion (peak ground acceleration, peak ground velocity, and peak ground displacement)
- Duration of strong motion
- Frequency content

Each of these parameters influences the response of a structure. Peak ground motion primarily influences the vibration amplitudes. Duration of strong motion has a pronounced effect on the severity of shaking. A ground motion with a moderate peak acceleration and long duration may cause more damage than a ground motion with a larger acceleration and a shorter duration. Frequency content and spectral shapes relate to frequencies or periods of vibration of a structure. In a structure, ground motion is most amplified when the frequency content of the motion and the vibration frequencies of the structure are close to each other. Each of these characteristics is briefly discussed below.

32.1.3.1 Peak Ground Acceleration

Peak ground acceleration has been widely used to scale earthquake design spectra and acceleration-time histories. As will be discussed later, recent studies recommend that in addition to peak ground acceleration, peak ground velocity, and displacement should be used for scaling purposes.

32.1.3.2 Duration of Strong Motion

Several investigators have proposed procedures for computing the strong-motion duration of an accelerogram. Page et al. (1972) and Bolt (1969) proposed the **bracketed duration**, which is the time interval between the first and the last acceleration peaks greater than a specified value (usually 0.05 g). Trifunac and Brady (1985) defined the duration of the strong motion as the time interval in which a significant contribution to the integral of the square of the acceleration ($\int a^2 dt$, referred to as the *accelerogram intensity*) takes place. They selected the time interval between the 5% and the 95% contributions as the duration of strong motion. The noted procedures usually result in different values for the duration of strong motion. This is to be expected, as the procedures are based on different criteria. Because there is no standard definition of strong-motion duration, the selection of a procedure for computing it for a study depends on the purpose of the study. The bracketed duration proposed in Page et al. (1972) and Bolt (1969) may be more appropriate when computing elastic and inelastic response.

32.1.3.3 Frequency Content

The frequency content of ground motion can be examined by transforming the motion from time domain to frequency domain through a Fourier transform. The Fourier amplitude spectrum and power spectral density, which are based on this transformation, may be used to characterize the frequency content. For further discussion regarding frequency content, the reader is encouraged to consult *The Seismic Design Handbook* (Naeim, 1989). When the power spectral density of ground motion at a site is established, random-vibration methods may be used to formulate probabilistic procedures for computing the response of structures.

32.1.4 Factors Influencing Ground Motion

Earthquake ground motion and its duration at a particular location are influenced by a number of factors, the most important being: (1) earthquake magnitude, (2) distance of the source of energy release (epicentral distance or distance from causative fault), (3) local soil conditions, (4) variation in geology and propagation of velocity along the travel path, and (5) earthquake-source conditions and mechanism (fault type, stress conditions, stress drop). Past earthquake records have been used to study some of these influences. Although the effect of some of these parameters, such as local soil conditions and distance from source of energy release, are fairly well understood and documented, the influence of the source mechanism and the variation of geology along the travel path are more complex and difficult to quantify. Several of these influences are interrelated; consequently, it is difficult to discuss them individually without incorporating the others. Some of these influences are discussed below.

32.1.4.1 Distance

The variation of ground motion with distance to the source of energy release has been studied by many investigators. In most studies, peak ground motion (usually peak ground acceleration) is plotted as a function of distance. A smooth curve based on a regression analysis is fitted to the data, and the curve or its equation is used to predict the expected ground motion as a function of distance. These relationships, referred to as *motion attenuation*, are sometimes plotted independently of the earthquake magnitude. This was the case in earlier studies because of the lack of sufficient numbers of earthquake records; however, with the availability of a large number of records, particularly during the 1971 San Fernando earthquake and subsequent seismic events, the database for attenuation studies was increased and a number of investigators reexamined their earlier studies, modified their proposed relationships for estimating peak accelerations, and included earthquake magnitude as a parameter. Donovan (1973)

TABLE 32.1 Typical Attenuation Relationships

Data Source	Relationships	Ref.
1 San Fernando earthquake, February 9, 1971	$a = 190/R^{1.83}$	Donovan (1973)
2 California earthquake	$a = \frac{y_0}{1 + (R'/h)^2}$ where $\log y_0 = -(\bar{b} + 3) + 0.81m - 0.027m^2$, where \bar{b} is a site factor	Blume et al. (1992)
3 California and Japanese earthquakes	$a = \frac{0.0051}{\sqrt{T_G}} 10^{0.61m - P \log R + Q}$ where $Q = 0.167 - 1.83/R$; T_G = fundamental period of site	Yamabe and Kanai (1988)
4 Cloud (1963)	$a = \frac{0.0069e^{1.64m}}{1.1e^{1.1m} + R^2}$	Milne and Davenport (1969)
5 Cloud (1963)	$a = 1.24e^{0.67m}/(R + 25)^2$	Esteva (1969)
6 USC and USGS	$\log a = \frac{6.5 - 2 \log(R' + 80)}{981}$	Cloud and Perez (1967)
7 303 instrumental values	$a = 1.325e^{0.67m}/(R + 25)^{1.6}$	Donovan (1973)
8 Western U.S. records	$a = 0.093e^{0.8m}/(R + 400)$	Donovan (1973)
9 U.S., Japan, etc.	$a = 1.35e^{0.58m}/(R + 25)^{1.52}$	Donovan (1973)
10 Western U.S. records, USSR, Iran	$\ln a = 3.99 + 1.28m - 1.75 \ln [R + 0.147e^{0.732m}]$	Campbell (1997)
11 Western U.S. records, worldwide	$\log a = -1.02 + 0.249m - \log (R^2 + 7.3^2)^{1/2} - 0.00255(R^2 + 7.3^2)^{1/2}$	Idriss (1993)
12 Western U.S. records	$\ln a = \ln \alpha(m) - \beta(m) \ln(R + 20)$ where m = surface-wave magnitude, $m \geq 6$; local magnitude, $m < 6$; R = smallest distance to source, $m \geq 6$; hypocentral distance, $m < 6$; $\alpha(m)$ and $\beta(m)$ are magnitude-dependent coefficients	Seed and Idriss (1982)
13 Italian records	$\log a = -1.562 + 0.306m - \log(R^2 + 5.8^2)^{1/2} + 0.169S$ where $S = 1.0$ for soft sites and 0 for rock	Sabetta and Pugliese (1987, 1996)

Note: Acceleration a is in g; distance to causative fault R is in kilometers; epicentral distance R' is in miles; local depth h is in miles.

compiled a database of more than 500 recorded accelerations from seismic events in the United States, Japan, and elsewhere, and later increased it to more than 650. A plot of peak ground acceleration vs. fault distance for different earthquake magnitudes from his database shows that, for a good portion of the data, the peak acceleration decreases as the distance from the source of energy release increases. It has been reported by Housner (1965), Donovan (1973), and Seed and Idriss (1982) that at distances away from the fault or the source of energy release (far field), the earthquake magnitude influences the attenuation, whereas at distances close to the fault (near field) the attenuation is affected by smaller earthquake magnitudes and not by the larger ones. The majority of attenuation studies and the relationships presented in Table 32.1 are mainly from data in the western United States. It is believed by several seismologists that ground acceleration attenuates more slowly in the eastern United States and eastern Canada. The variation of peak ground velocity with distance from the source of energy release (velocity attenuation) has also been studied by several investigators. Velocity attenuation curves have similar shapes and follow similar trends to the acceleration attenuation; however, velocity attenuates somewhat faster than acceleration, and, unlike acceleration attenuation, velocity attenuation depends on soil condition.

FIGURE 32.1 Comparison of attenuation curves for rock sites and the Imperial Valley earthquake of 1979. (Adapted from Seed, H.B. and Idris, I.M., *Ground Motions and Soil Liquefaction during Earthquakes*, Earthquake Engineering Research Institute, Berkeley, CA, 1982.)

Distance also influences the duration of strong motion. Correlation of the duration of strong motion with epicentral distance has been studied by Page et al. (1972), Trifunac and Brady (1975), Krinitzsky and Chang, and others. Page et al. (1972), using the bracketed duration, concluded that for a given magnitude the duration decreases with an increase in the distance from the source.

32.1.4.2 Site Geology

Soil conditions influence ground motion and its attenuation. Several investigators, such as Boore et al. (1978, 1980) and Seed and Idriss (1982), have presented attenuation curves for soil and rock. According to Boore et al., the peak horizontal acceleration is not appreciably affected by soil condition (it is nearly the same for rock and for soil). Seed and Idriss compared the acceleration attenuation for rock from earthquakes with Richter magnitudes of approximately 6.6 with that for alluvium from the 1979 Imperial Valley earthquake (Richter magnitude, 6.8). Their comparison, shown in Figure 32.1, indicates that, at a given distance from the source of energy release, peak accelerations on rock are somewhat greater than those on alluvium. The effect of soil condition on peak acceleration is illustrated in Figure 32.2. According to this figure, the difference in acceleration in rock and in stiff soil is practically negligible. There seems to be general agreement among various investigators that soil condition has a pronounced influence on velocities and displacements. Larger peak horizontal velocities are more likely to be expected in soil than in rock.

32.1.4.3 Magnitude

As expected, at a given distance from the source of energy release, larger earthquake magnitudes result in larger peak ground accelerations, velocities, and displacements. Because of the lack of adequate data for earthquake magnitudes greater than approximately 7.5, the effect of magnitude on peak ground motion and duration is generally determined through extrapolation of data from earthquake magnitudes smaller than 7.5.

FIGURE 32.2 Relationship between peak accelerations of rock and soil. (Adapted from Seed, H.B. and Idriss, I.M., *Ground Motions and Soil Liquefaction during Earthquakes*, Earthquake Engineering Research Institute, Berkeley, CA, 1982.)

32.1.5 Evaluating Seismic Risk at a Site

Seismic-risk evaluation is based on information from three sources: (1) the recorded ground motion, (2) the history of seismic activity in the vicinity of the site, and (3) the geological data and fault activities of the region. For most regions of the world this information, particularly that from the first source, is very limited and may not be sufficient to predict the size and recurrence intervals of future earthquakes. Nevertheless, earthquake engineers have relied on this limited information to establish some acceptable levels of risk. Seismic-risk analysis usually begins with developing mathematical models that are used to estimate the recurrence intervals of future earthquakes with certain magnitudes and/or intensities. These models, together with the appropriate attenuation relationships, are commonly utilized to estimate ground-motion parameters such as the peak acceleration and velocity corresponding to a specified probability and return period. The provisions of the International Building Code (IBC) use the spectral accelerations determined from maximum considered earthquake ground motion maps prepared by the U.S. Geological Survey (USGS). The ground motion accelerations are modified for specific site characteristics to determine actual design-level accelerations. The USGS maps are extremely detailed and may be referenced in ASCE 7-05 or on the USGS website. For a discussion regarding the use of such mapped accelerations, refer to Section 32.2.1.1.

32.1.6 Estimating Ground Motion

Seismic-risk procedures and attenuation relationships are primarily developed for estimating the expected peak horizontal acceleration at the site. A statistical summary of the peak ground acceleration ratios for all four soil categories (rock, 30 ft of alluvium underlain by rock, 30 to 200 ft of alluvium underlain by rock, alluvium) is presented in Table 32.2. The table includes the ratio of the smaller to the larger of the two peak horizontal accelerations and the ratio of the vertical to the larger of the two peak horizontal accelerations. In each column, the ratios are generally close to each other, indicating that the soil condition does not influence the acceleration ratios. The 2/3 ratio of the vertical to horizontal acceleration, which has been recommended by Newmark and has been employed in seismic design, is closer to the 84.1 percentile than to the 50 percentile ratio. Although the 2/3 ratio is conservative, its use has been justified as taking into account variations greater than the median and uncertainties in the ground motion in the vertical direction.

TABLE 32.2 Summary of Peak Ground Acceleration Ratios (Lognormal Distribution)

Soil Category	a_s/a_l			a_v/a_l		
	Percentile		Mean	Percentile		Mean
	50	84.1		50	84.1	
Rock	0.81	0.99	0.82	0.48	0.69	0.52
<30 ft of alluvium underlain by rock	0.89	0.98	0.89	0.47	0.62	0.46
30–200 ft of alluvium underlain by rock	0.82	0.96	0.83	0.40	0.66	0.46
Alluvium	0.75	0.96	0.79	0.42	0.61	0.45

Note: a_s is the smaller of the two horizontal components; a_l is the larger peak acceleration of the two horizontal components; a_v is the peak acceleration of the vertical component.

32.2 International Building Code (IBC 2006)

32.2.1 IBC Design Criteria

The International Building Code (ICC, 2006) references the provisions of ASCE 7-05 (ASCE, 2005) for lateral seismic loads. The ASCE 7-05 seismic design criteria are in turn based on the *NEHRP Recommended Provisions for Seismic Regulations for New Buildings and Other Structures* (FEMA, 2003). The provisions and commentary may be found at www.bassconline.org. The basic guideline of the IBC provisions is that a minor seismic event should cause little or no damage, and a major seismic event should not result in the collapse of the structure. Accordingly, the building is expected to behave elastically when subjected to frequently occurring earthquakes and exhibit inelastic behavior when influenced only by infrequent strong earthquakes. Most low-rise concrete buildings fall into the regular structure type of the International Building Code and accordingly are designed for a loading condition resulting from equivalent static lateral force. This static load depends on the site geology and soil characteristics, the building occupancy, the building configuration and height, and the structural system being used to support the lateral load. It is important to note that code static loads are no more than one quarter to one third of the expected earthquake action. This can be justified in concrete structures where the anticipated cracking results in increased energy absorption only where ductility in each resisting member and between all the resisting members can be maintained.

32.2.1.1 Mapped Acceleration Parameters

Chapter 22 of ASCE 7-05 contains the mapped maximum considered earthquake (MCE) ground motion parameters S_s and S_1 . Both S_s and S_1 are spectral response acceleration parameters with 5% damping; S_s is determined from a 0.2-second response acceleration, and S_1 is determined from a 1-second response acceleration. Chapter 22 provides detailed maps developed by the U.S. Geological Survey (USGS), but it is not practical to determine site parameters from the maps provided. The recommended method of obtaining these parameters is to use the Ground Motion Parameter Calculator, provided on the USGS website (<http://earthquake.usgs.gov/research/hazmaps/>), which allows for the input of a Zip Code or a latitude and longitude to obtain the response parameters. It is recommended that the latitude and longitude for the specific site be used, as the response parameters can vary significantly over the region of an entire Zip Code. Websites such as <http://terraserwer.microsoft.com/> may be used to obtain latitude and longitude information for a particular address.

32.2.1.2 Site Class

Site class has replaced the term *soil profile type*, which was used in past codes such as the 1997 Uniform Building Code. Because the soil type on which a structure is founded has a great impact on the ground motion at the site, different soil types are assigned values, depending on their stiffness, from Site Class A for rocklike material to Site Class F for a soil profile that requires a site-specific analysis. Table 32.3 lists the site coefficients for different soil types. Site class should not be confused with *seismic design*

TABLE 32.3 Site Classification

Site Class		v_s (ft/sec)	N or N_{ch}	S_u (psf)
A	Hard rock	>5,000	NA	NA
B	Rock	2500 to 5000	NA	NA
C	Very dense soil and soft rock	1200 to 2500	>50	>2000 psf
D	Stiff soil	600 to 1200	15–50	1000–2000 psf
E	Soft clay soil	<600	<15	<1000 psf
		Any profile with more than 10 ft of soil having the following characteristics:		
		-Plasticity index $PI > 20$,		
		-Moisture content $w \geq 40\%$, and		
		-Undrained shear strength $s_u < 500$ psf		
F	Soils requiring site response analysis in accordance with Section 21.1 of ASCE 7-05	See Section 20.3.1 of ASCE 7-05.		

Note: For SI units, 1 ft/sec = 0.3048 m/sec; 1 lb/ft² = 0.0479 kN/m².

Source: ASCE, *Minimum Design Loads for Buildings and Other Structures*, ASCE 7-05, American Society of Civil Engineers, Reston, VA, 2005. With permission.

category, as both use the letters A through F to define different soil types or seismic design categories. Site class is one of the elements used to determine the seismic design category. When not enough information is available to determine the site class, Site Class D shall be used except when the authority having jurisdiction determines that Site Class E or Site Class F is appropriate.

32.2.1.3 Site Coefficients and Adjusted Maximum Considered Earthquake Spectral Response Acceleration Parameters

The mapped acceleration parameters contained in Chapter 22 of ASCE 7-05 are based on Site Class B. When the actual site class varies from Site Class B, the acceleration parameters must be modified based on the actual site class; for example, S_s must be multiplied by an adjustment factor (F_a) to determine S_{MS} , the maximum considered earthquake (MCE) spectral response acceleration at short periods adjusted for site class effects. The same holds true for the MCE spectral acceleration at a period of 1 second; S_1 is multiplied by F_v to determine S_{M1} . Refer to Table 32.4 and Table 32.5 for the site coefficients F_a and F_v , respectively.

32.2.1.4 Design Spectral Acceleration Parameters

The design earthquake spectral response acceleration parameters are determined by multiplying the modified MCE spectral response acceleration parameters by 2/3:

$$S_{DS} = \frac{2}{3}S_{MS}, \quad S_{D1} = \frac{2}{3}S_{M1}$$

32.2.1.5 Design Response Spectrum

When required by ASCE 7-05 and the IBC, the design response spectrum shall be developed as shown in Figure 32.3.

32.2.1.6 Importance Factor and Occupancy Category

The importance factor (I) depends on the occupancy category of a given structure. The International Building Code and ASCE 7-05 distinguish between four different categories:

- Buildings and other structures that represent a low hazard to human life in the event of failure
- All other structures besides those listed in Occupancy Categories I, III, and IV
- Buildings and structures that represent a substantial hazard to human life in the event of failure
- Essential facilities and structures containing highly toxic substances

TABLE 32.4 Site Coefficient F_a

Site Class	Mapped Maximum Considered Earthquake Spectral Response Acceleration Parameter at a Short Period				
	$S_s \leq 0.25$	$S_s = 0.5$	$S_s = 0.75$	$S_s = 1.0$	$S_s \geq 1.25$
A	0.8	0.8	0.8	0.8	0.8
B	1.0	1.0	1.0	1.0	1.0
C	1.2	1.2	1.1	1.0	1.0

Essential facilities, in addition to having an importance factor of 1.5, require special construction review, inspection, and observation procedures. It is argued that the additional measures can improve performance more effectively than solely relying on increased design force levels. Refer to Table 32.6 for the detailed description of the various occupancy categories. Refer to Table 32.7 for importance factor I based on the occupancy category.

TABLE 32.6 Occupancy Category of Buildings and Other Structures for Flood, Wind, Snow, Earthquake, and Ice Loads

Nature of Occupancy	Occupancy Category
Buildings and other structures that represent a low hazard to human life in the event of failure, including, but not limited to: Agricultural facilities Certain temporary facilities Minor storage facilities	I
All buildings and other structures except those listed in Occupancy Categories I, III, and IV	II
Buildings and other structures that represent a substantial hazard to human life in the event of failure, including, but not limited to: Buildings and other structures where more than 300 people congregate in one area Buildings and other structures with daycare facilities with a capacity greater than 150 Buildings and other structures with elementary school or secondary school facilities with a capacity greater than 250 Buildings and other structures with a capacity greater than 500 for colleges or adult education facilities Healthcare facilities with a capacity of 50 or more resident patients but not having surgery or emergency treatment facilities Jail and detention facilities	III
Buildings and other structures, not included in Occupancy Category IV, with potential to cause a substantial economic impact and/or mass disruption of day-to-day civilian life in the event of failure, including, but not limited to: Power-generating stations ^a Water-treatment facilities Sewage treatment facilities Telecommunication centers	
Buildings and other structures not included in Occupancy Category IV (including, but not limited to, facilities that manufacture, process, handle, store, use, or dispose of such substances as hazardous fuels, hazardous chemicals, hazardous waste, or explosives) containing sufficient quantities of toxic or explosive substances to be dangerous to the public if released	
Buildings and other structures containing toxic or explosive substances shall be eligible for classification as Occupancy Category II structures if it can be demonstrated to the satisfaction of the authority having jurisdiction by a hazard assessment as described in Section 1.5.2 that a release of the toxic or explosive substances does not pose a threat to the public.	
Buildings and other structures designated as essential facilities, including, but not limited to: Hospitals and other healthcare facilities having surgery or emergency treatment facilities Fire, rescue, ambulance, police station and emergency vehicle garages Designated earthquake, hurricane, or other emergency shelters Designated emergency preparedness, communication, and operation centers and other facilities required for emergency response Power generating stations and other public utility facilities required in and emergency	IV
Ancillary structures (including, but not limited to, communication towers, fuel storage tanks, cooling towers, electrical substation structures, fire water storage tanks or other structures housing or supporting water or other fire-suppression material or equipment) required for operation of Occupancy Category IV Structures during an emergency	
Aviation control towers, air traffic control centers, and emergency aircraft hangars	
Water-storage facilities and pump structures required to maintain water pressure for fire suppression	
Buildings and other structures having critical national defense functions	
Buildings and other structures (including, but not limited to, facilities that manufacture, process, handle, store, use, or dispose of such substances as hazardous fuels, hazardous chemicals, or hazardous waste) containing highly toxic substances where the quantity of the material exceeds a threshold quantity established by the authority having jurisdiction	
Buildings and other structures containing highly toxic substances shall be eligible for classification as Occupancy Category II structures if it can be demonstrated to the satisfaction of the authority having jurisdiction by a hazard assessment as described in Section 1.5.2 that a release of the highly toxic substances does not pose a threat to the public. This reduced classification shall not be permitted if the buildings or other structures also function as essential facilities.	

^a Cogeneration power plants that do not supply power on the national grid shall be designated Occupancy Category II.

32.2.1.7 Seismic Design Category

Structures shall be assigned the more severe seismic design category as determined from Table 32.8 or Table 32.9 regardless of the period of vibration of the structure. In addition, when the mapped spectral response acceleration parameter at the 1-second period (S_1) is greater than or equal to 0.75, then the structures in Occupancy Categories I, II, or III shall be assigned to Seismic Design Category E, and structures in Occupancy Category IV shall be assigned to Seismic Design Category F. There are exceptions that allow for the seismic design category to be determined from Table 32.8 alone. To use this exception, S_1 must be less than 0.75, and all of the following requirements must be met:

- The approximate fundamental period of vibration (T_a), as determined by Equation 32.4 in each of the two orthogonal directions, is less than $0.8T_s$, where $T_s = S_{D1}/S_{DS}$.
- The fundamental period of the structure that is used to calculate the story drift in the two orthogonal directions is less than T_s .
- The seismic response coefficient (C_s) is determined by Equation 32.2.
- The diaphragms are rigid or, where diaphragms are considered flexible, the spacing between vertical elements of the lateral-force-resisting system does not exceed 40 feet.

32.2.2 Design Requirements for Seismic Design Category A

Structures designated to Seismic Design Category A are designed for minimal seismic forces. A lateral force of 1% of the dead load of each level shall be applied in each of two orthogonal directions independently. Load path connections must be designed to transfer the lateral forces induced by the elements being connected. Smaller portions of a structure are required to be tied to the remainder of the structure with a strength of at least 5% of the weight of the smaller portion. Connections to supporting elements require a positive connection to resist a horizontal force acting parallel to the member being connected. This positive connection may be obtained by connecting an element to slabs designed to act as diaphragms, but the supporting element must then be connected to the diaphragm with a connection strength of 5% of the dead plus live load reaction. Concrete and masonry walls are required to be anchored to all floors and the roof, as well as members that provide lateral support for the wall or that are supported by the wall.

32.2.3 Design Requirements for Seismic Design Categories B, C, D, E, and F

Similar to Seismic Design Category A, Seismic Design Categories B through F have some minimum requirements with respect to member design, connection design, and load path. These requirements may be found at the beginning of Chapter 12 of ASCE 7-05. The design of building structures assigned to Seismic Design Categories B through F requires the following steps:

- Determine the structural system or systems (may include a combination of systems in different directions, in the same direction, or vertical combinations).
- Determine if any structural irregularities exist.
- Determine redundancy factor ρ if the structure is assigned to Seismic Design Categories D through F.
- Determine the appropriate analytical procedure (i.e., equivalent lateral force analysis, modal response spectrum analysis, or seismic response history procedure).
- Apply the appropriate seismic load combinations to determine member design forces.
- Determine the diaphragm, chord, and collector design requirements.
- Check allowable story drift and determine building separation requirements, if necessary.
- Check deformation compatibility of members not included in the seismic-force-resisting system.
- Address foundation design requirements.
- Address material specific seismic design and detailing requirements of the structural system.

32.2.3.1 Structural System Selection

The maximum elastic response acceleration of a structure during a severe earthquake can be several times the magnitude of the maximum ground acceleration and depends on the mass and stiffness of the structure and the amplitude of the damping. Because it is unnecessary to design a structure to respond in the elastic range to the maximum seismic inertia forces, it is of the utmost importance that a well-designed structure be able to dissipate seismic energy by inelastic deformations in certain localized regions of the lateral-force-resisting system. This translates into accomplishing flexural yielding of the members and avoiding all forms of brittle failure. The code-specified design seismic force recognizes such inelastic behavior and damping and scales down the inertia forces corresponding to a fully elastic response based on the structural system used. This is accounted for in the response modification factor (R). The structural systems for buildings and the corresponding R values are listed in Table 32.10 and are defined as follows:

- *Bearing wall system*—A structural system without a complete vertical-load-carrying frame. Bearing walls provide support for all or most gravity loads. Resistance to lateral load is provided by shear walls or light-frame walls with flat-strap bracing. In Seismic Design Categories D, E, and F, concrete and masonry shear walls must be specially detailed to satisfy IBC requirements. These special reinforced-concrete or masonry shear walls are limited to a height of 160 feet in Seismic Design Categories D and E, while they are limited to a height of 100 feet in Seismic Design Category F.

- *Building frame system*—A structural system with an essentially complete frame providing support for gravity loads. Resistance to lateral load is provided by shear walls or braced frames. Shear walls in Seismic Design Categories D, E, and F are required to be specially designed and detailed to satisfy the IBC requirements. In addition, other structural elements not designated part of the lateral-load-resisting system must be able to sustain their gravity load-carrying capacity at a lateral displacement equal to a multiple times the computed elastic displacement of the lateral-force-resisting system under code-specified design seismic forces. The IBC restricts the building frame system to a maximum height of 160 feet for Seismic Design Categories D and E but lowers the limit to 100 feet for Seismic Design Category F.
- *Moment-resisting frame system*—A structural system with an essentially complete frame providing support for gravity loads. Moment-resisting frames provide resistance to lateral loads primarily by flexural action of members. In Seismic Design Category B, the moment-resisting frames can be ordinary moment-resisting frames (OMRFs) proportioned to satisfy the IBC requirements. In Seismic Design Category C, reinforced-concrete frames resisting forces induced by earthquake motions at minimum must be intermediate moment-resisting frames (IMRFs). In Seismic Design Categories D, E, and F, reinforced-concrete frames resisting forces induced by earthquake motions must be special moment-resisting frames (SMRFs).
- *Dual system*—Structural system with the following features: (1) an essentially complete frame that provides support for gravity loads; (2) resistance to lateral load provided by shear walls or braced frames and moment-resisting frames (SMRFs and IMRFs), with the moment-resisting frames designed to independently resist at least 25% of the design base shear; and (3) designed to resist total design base shear in proportion to relative rigidities considering the interaction of the dual system at all levels.
- *Shear wall-frame interactive system*—A structural system with ordinary reinforced-concrete moment frames and ordinary reinforced-concrete shear walls. This system is permitted only in Seismic Design Category B.
- *Cantilevered column system*—A structural system consisting of cantilevered column elements detailed to conform to the requirements of various moment frame systems.

32.2.3.2 Combinations of Framing Systems in Different Directions

Any combination of moment-resisting frame systems, dual systems, building frame systems, or bearing wall systems may be used to resist seismic forces in each of the two orthogonal directions of the structure. Where different systems are used, the respective R , C_d , and Ω_o coefficients shall apply to each system, including the limitations on system use contained in Table 32.10.

32.2.3.3 Combination of Framing Systems in the Same Direction

Where different seismic-force-resisting systems are used in the same direction but do not meet the requirements of a dual system, the more stringent response modification factor, deflection amplification factor, and overstrength factor shall be used in the analysis and design. Resisting elements are permitted to be designed for the least value of R for the different structural systems found in each independent line of resistance if the following three conditions are met:

- Occupancy Category I or II building
- Two stories or less in height
- Use of light-frame construction or flexible diaphragms

32.2.3.4 Vertical Combinations

The International Building Code requires that the value of the response modification factor (R) used in the design of any story be less than or equal to the value of R used in the given direction for the story above. The deflection amplification factor (C_d) and the system overstrength factor (Ω_o) used for the design of any story shall not be less than the largest value of these factors used in the given direction for the story above. Exceptions to these requirements include:

F	Shear Wall-Frame Interactive System with Ordinary Reinforced Concrete Moment Frames and Ordinary Reinforced Concrete Shear Walls	12.2.5.10, 14.2	4-1/2	2-1/2	NL	NP	NP

^a Response modification coefficient (R) for use throughout the standard. Note that R reduces forces to a strength level, not an allowable stress level.

^b Deflection amplification factor (C_d) for use in ASCE 7-05, Sections 12.8.6, 12.8.7, and 12.9.2

^c NL = not limited and NP = not permitted. For metric units, use 30.5 m for 100 ft and use 48.8 m for 160 ft. Heights are measured from the base of the structure as defined in ASCE 7-05, Section 11.2.

^d See ASCE 7-05, Section 12.2.5.4, for description of building systems limited to buildings with a height of 240 ft (73.2 m) or less.

^e See ASCE 7-05, Section 12.2.5.4, for building systems limited to buildings with a height of 160 ft (48.8m) or less.

^f Ordinary moment frame is permitted to be used in lieu of intermediate moment frame for Seismic Design Categories B or C.

^g The tabulated value of the overstrength factor (Ω_o) is permitted to be reduced by subtracting one half for structures with flexible diaphragms but shall not be taken as less than 2.0 for any structure.

^h See ASCE 7-05, Sections 12.2.5.6 and 12.2.5.7, for limitations for steel OMFs and IMFs in structures assigned to Seismic Design Category D or E.

ⁱ See ASCE 7-05, Sections 12.2.5.8 and 12.2.5.9, for limitations for steel OMFs and IMFs in structures assigned to Seismic Design Category F.

^j Steel ordinary concentrically braced frames are permitted in single-story storage building up to height of 60 ft (18.3 m) where the dead load of the roof does not exceed 20 psf (0.96kN/m²) and in penthouse structures.

^k Increase in height to 45 ft (13.7 m) is permitted for single story storage warehouse facilities.

Source: Adapted from ASCE, *Minimum Design Loads for Buildings and Other Structures*, ASCE 7-05, American Society of Civil Engineers, Reston, VA, 2005, Table 12.2-1. With permission.

- Rooftop structures not exceeding two stories in height and 10% of the weight of the entire structure
- Other supported structural systems with a weight equal to or less than 10% of the weight of the entire structure
- Detached one- and two-family dwellings of light-frame construction

A two-stage equivalent lateral force procedure is permitted to be used for structures having a flexible upper portion supported by a rigid lower portion, provided that the design of the structure complies with the following:

- The stiffness of the lower portion must be at least 10 times the stiffness of the upper portion.
- The period of the entire structure shall not be greater than 1.1 times the period of the upper portion considered as a separate structure fixed at the base.
- The flexible upper portion shall be designed as a separate structure using the appropriate values of R and ρ .
- The rigid lower portion shall be designed as a separate structure using the appropriate values of R and ρ . The reactions from the upper portion shall be those determined from analysis of the upper portion amplified by the ratio of the R/ρ of the upper portion over R/ρ of the lower portion. This ratio shall not be less than 1.0.

32.2.3.5 Combination Framing Detailing Requirements

Structural components that are common to different framing systems used to resist seismic motions in any direction shall be detailed in accordance with the requirements of ASCE 7-05, Chapter 12, for the highest response modification factor (R) of the connected framing systems. More stringent detailing is required with the higher response modification factor.

32.2.3.6 System-Specific Requirements

A series of system-specific requirements either imposes additional limitations on system use or notes exceptions to system use in particular seismic design categories. These requirements are included in ASCE 7-05, Section 12.2.5.

32.2.3.7 Diaphragm Flexibility

The relative stiffness of the diaphragms of a structure shall be considered in the analysis unless the diaphragms can be idealized as rigid or flexible. Certain types of construction may be idealized as either flexible or rigid diaphragms. When the diaphragm cannot be idealized as flexible or rigid, the structural analysis performed shall explicitly include the stiffness of the diaphragm. The inclusion of the diaphragm stiffness in the analysis is often referred to as *semirigid modeling*, which is often available as an option in commercially available structural analysis software. Concrete slabs and concrete-filled metal deck slabs with span-to-depth ratios of 3 or less in structures with no horizontal irregularities are allowed to be idealized as rigid diaphragms.

32.2.3.8 Structural Irregularities

The IBC and ASCE 7-05 require that a structure be designated as *regular* or *irregular*. Regular structures have no significant physical discontinuities in plan or vertical configurations or in their lateral-force-resisting systems. Two assumptions apply for regular structures. First, the equivalent static force distribution provides a conservative envelope of the forces and deformations due to the actual dynamic response. Second, the cyclic inelastic deformation demands during a major level of seismic ground motion will be reasonably uniform in all elements. Irregular structures are those with irregular features as described in Table 32.11 and Table 32.12. Vertical irregularities are defined as a distribution of mass, stiffness, or strength that results in lateral forces or deformations, over the height of the structure, that are significantly different from the linearly varying distribution obtained from an equivalent lateral force analysis. Plan irregularities are encountered where diaphragm characteristics create significant diaphragm deformations or stress concentrations. As will be seen in the next section, only structures with certain types of irregularities require a dynamic analysis.

TABLE 32.11 Horizontal Structural Irregularities

Irregularity Type and Description		ASCE 7-05 Reference Section	Seismic Design Category Application
1a	<i>Torsional irregularity</i> is defined to exist where the maximum story drift, computed including accidental torsion, at one end of the structure transverse to an axis is more than 1.2 times the average of the story drifts at the two ends of the structure. Torsional irregularity requirements in the reference sections apply only to structures in which the diaphragms are rigid or semirigid.	12.3.3.4 12.8.4.3 12.7.3 12.12.1 Table 12.6-1 16.2.2	D, E, and F C, D, E, and F B, C, D, E, and F C, D, E, and F B, C, D, E, and F
1b	<i>Extreme torsional irregularity</i> is defined to exist where the maximum story drift, computed including accidental torsion, at one ends of the structure transverse to an axis is more than 1.4 times the average of the story drifts at the two ends of the structure. Extreme torsional irregularity requirements in the reference sections apply only to structures in which the diaphragms are rigid or semirigid.	12.3.3.1 12.3.3.4 12.7.3 12.8.4.3 12.12.1 Table 12.6-1 16.2.2	E and F D B, C, and D C and D D B, C, and D
2	<i>Reentrant corner irregularity</i> is defined to exist where both plan projections of the structure beyond a reentrant corner are greater than 15% of the plan dimension of the structure in the given direction.	12.3.3.4 Table 12.6-1	D, E, and F D, E, and F
3	<i>Diaphragm discontinuity irregularity</i> is defined to exist where there are diaphragms with abrupt discontinuities or variations in stiffness, including those having cutout or open areas greater than 50% of the gross enclosed diaphragm area, or changes in effective diaphragm stiffness of more than 50% from one story to the next.	12.3.3.4 Table 12.6-1	D, E, and F D, E, and F
4	<i>Out-of-plane offsets irregularity</i> is defined to exist where there are discontinuities in a lateral force-resistance path, such as out -of-plan offsets of the vertical elements.	12.3.3.4 12.3.3.3 12.7.3 Table 12.6-1 16.2.2	D, E, and F B, C, D, E, and F B, C, D, E, and F D, E, and F B, CD, E, and F
5	<i>Nonparallel systems irregularity</i> is defined to exist where the vertical lateral-force-resisting elements are not parallel to or symmetric about the major orthogonal axes of the seismic-force-resisting system.	12.5.3 12.7.3 Table 12.6-1 16.2.2	C,D, E and F B, C, D, E, and F D, E, and F B, C, D, E, and F

Source: ASCE, *Minimum Design Loads for Buildings and Other Structures*, ASCE 7-05, American Society of Civil Engineers, Reston, VA, 2005. With permission.

In Seismic Design Categories E and F, structures with horizontal irregularity Type 1b or vertical irregularities Type 1b, Type 5a, and Type 5b are not permitted. Structures having vertical irregularity Type 5b in Seismic Design Category D are not permitted. Structures with a Type 5b vertical irregularity are not permitted to exceed 2 stories or 30 feet in height except when the weak story is designed to resist the forces determined by the special seismic load combinations including Ω_O . Overturning moments on discontinuous shear-resisting elements are to be carried as loads to the foundation. In Seismic Design Categories B through F, columns, beams, trusses, or slabs supporting the overturning forces of discontinuous shear walls or frames of structures are to be designed to resist the axial forces resulting from the special seismic load combinations including Ω_O . The columns carrying these factored loads may be designed considering the maximum force that can be transferred from the supported element above and must meet special detailing requirements to ensure their ductile behavior under cyclic loading.

32.2.3.9 Analysis Procedure Selection

The IBC and ASCE 7-05 recognize three different analysis procedures for the determination of seismic effects on structures. Refer to Table 32.13 for the applicability of each of the three analysis options. The equivalent lateral force analysis procedure is allowed when certain criteria of building period, occupancy, and regularity are met; the modal response spectrum analysis (dynamic analysis) procedure is always permissible for design. The third analysis option is the seismic response history procedure, which is

TABLE 32.12 Vertical Structural Irregularities

Irregularity Type and Description		ASCE 7-05 Reference Section	Seismic Design Category Application
1a	<i>Stiffness-soft story irregularity</i> is defined to exist where there is a story in which the lateral stiffness is less than 70% of that in the story above or less than 80% of the average stiffness of the three stories above.	Table 12.6-1	D,E, and F
1b	<i>Stiffness-extreme soft story irregularity</i> is defined to exist where there is a story in which the lateral stiffness is less than 60% of that in the story above or less than 70% of the average stiffness of the three stories above.	12.3.3.1 Table 12.6-1	E and F D, E, and F
2	<i>Weight (mass) irregularity</i> is defined to exist where the effective mass of any story is more than 150% of the effective mass of an adjacent story. A roof that is lighter than the floor below need not be considered.	Table 12.6-1	D, E, and F
3	<i>Vertical geometric irregularity</i> is defined to exist where the horizontal dimension of the seismic-force-resisting system in any story is more than 130% of that in an adjacent story.	Table 12.6-1	D, E, and F
4	<i>In-plane discontinuity in vertical lateral-force-resisting element irregularity</i> is defined to exist where an in-plane offset of the lateral-force-resisting element is greater than the length of those elements or there exists a reduction in stiffness of the resisting element in the story below.	12.3.3.3 12.3.3.4 Table 12.6-1	B, C, D, E, and F D, E, and F D, E, and F
5a	<i>Discontinuity in lateral strength-weak story irregularity</i> is defined to exist where the story lateral strength is less than 80% of that in the story above. The story lateral strength is the total lateral strength of all seismic resisting elements sharing the story shear for the direction under consideration.	12.3.3.1 Table 12.6-1	E and F D, E, and F
5b	<i>Discontinuity in lateral strength-extreme weak story irregularity</i> is defined to exist where the story lateral strength is less than 65% of that in the story above. The story strength is the total strength of all seismic resisting elements sharing the story shear for the direction under consideration.	12.3.3.1 12.3.3.2 Table 12.6-1	D, E, and F B and C D, E, and F

Source: ASCE, *Minimum Design Loads for Buildings and Other Structures*, ASCE 7-05, American Society of Civil Engineers, Reston, VA, 2005. With permission.

beyond the scope of this chapter. The scope of this chapter is primarily dedicated to the equivalent lateral force analysis procedure, but modal response spectrum analysis is briefly touched upon. Equivalent lateral force analysis is acceptable for use with all structures, regular or irregular, in Seismic Design Categories B and C. Equivalent lateral force analysis may be used for regular and irregular structures in Seismic Design Categories D, E, and F with a fundamental period of vibration, in each of the two orthogonal directions, less than $3.5T_s$, except when a Type 1a or Type 1b horizontal irregularity or Type 1a, Type 1b, Type 2 or Type 3 vertical irregularity exists. Additional structural characteristics that allow the use of the equivalent lateral force analysis procedure are noted in Table 32.13.

32.2.3.10 Redundancy

A redundancy factor (ρ) shall be assigned to the seismic-force-resisting system in each of two orthogonal directions for all structures. Redundancy factor ρ is permitted to equal 1.0 for the following:

- Structures assigned to Seismic Design Categories B or C
- Drift calculations and P-delta effects
- Design of nonbuilding structures that are not similar to buildings
- Design of collector elements, splices, and their connections for which the load combinations including the overstrength factor Ω_o are used
- Design of members or connections where the load combinations including the overstrength factor Ω_o are required for design

TABLE 32.13 Permitted Analytical Procedures

Seismic Design Category	Structural Characteristics	Equivalent Lateral Force Analysis (Section 32.2.4)	Modal Response Spectrum Analysis (Section 32.2.5)	Seismic Response History Procedures (ASCE 7-05, Chapter 16)
B, C	Occupancy Category I or II buildings of light-framed construction not exceeding 3 stories in height	P	P	P
	Other Occupancy Category I or II buildings not exceeding 2 stories in height	P	P	P
	All other structures	P	P	P
D, E, F	Occupancy Category I or II buildings of light-framed construction not exceeding 3 stories in height	P	P	P
	Other Occupancy Category I or II buildings not exceeding 2 stories in height	P	P	P
	Regular structures with $T < 3.5T_s$ and all structures of light-framed construction	P	P	P
	Irregular structures with $T < 3.5T_s$ and having only horizontal irregularities Type 2, 3, 4, or 5 of Table 32.11 or vertical irregularities Type 4, 5a, or 5b of Table 32.12	P	P	P
	All other structures	NP	P	P

Note: P, permitted; NP, no permitted.

Source: ASCE, *Minimum Design Loads for Buildings and Other Structures*, ASCE 7-05, American Society of Civil Engineers, Reston, VA, 2005.

- Diaphragm loads determined using Equation 32.18
- Structures with damping systems designed in accordance with ASCE 7-05, Chapter 18.

The redundancy factor (ρ) shall equal 1.3 for structures assigned to Seismic Design Categories D, E, or F, unless one of the following conditions is met, whereby ρ is permitted to be taken as 1.0:

- Each story resisting more than 35% of the base shear in the direction of interest shall comply with Table 32.14.
- Structures are regular in plan at all levels, provided that the seismic-force-resisting systems consist of at least two bays of seismic-force-resisting perimeter framing on each side of the structure in each orthogonal direction at each story resisting more than 35% of the base shear. The number of bays for a shear wall shall be calculated as the length of the shear wall divided by the story height or two times the length of the shear wall divided by the story height for light-frame construction.

32.2.4 Equivalent Lateral Force Procedure

The International Building Code and ASCE 7-05 require that structures be designed for seismic forces in each of the two orthogonal directions. Such forces may be assumed to act nonconcurrently in the direction of each principal axis of the structure except for structures with certain plan irregularities. Even though not all structures are permitted to be designed using the equivalent lateral force analysis procedure, the procedure is often used to help determine those structures that require more exhaustive analysis. When a dynamic analysis is to be preformed, an equivalent lateral force analysis generally has to be the first step of the process.

TABLE 32.14 Requirements for Each Story Resisting More Than 35% of the Base Shear

Lateral-Force-Resisting Element	Requirement
Braced frames	Removal of an individual brace, or connection thereto, would not result in more than a 33% reduction in story strength nor does the resulting system have an extreme torsional irregularity (horizontal structural irregularity Type 1b).
Moment frames	Loss of moment resistance at the beam-to-column connections at both ends of a single beam would not result in more than a 33% reduction in story strength nor does the resulting system have an extreme torsional irregularity (horizontal structural irregularity Type 1b).
Shear walls or wall pier with a height-to-length ratio greater than 1.0	Removal of a shear wall or wall pier with a height-to-length ratio greater than 1.0 within any story, or collector connections thereto, would not result in more than 33% reduction in story strength nor does the resulting system have an extreme torsional irregularity (horizontal structural irregularity Type 1b).
Cantilever columns	Loss of moment resistance at the base connections of any single cantilever column would not result in more than 33% reduction in story strength nor does the resulting system have an extreme torsional irregularity (horizontal structural irregularity Type 1b).
Other	No requirements.

32.2.4.1 Effective Seismic Weight (W)

The effective seismic weight of a building (W) is the total dead load and applicable portions of other loads:

- In occupancies where partition loads are used in the floor design, a load of not less than 10 psf shall be included.
- In occupancies such as storage and warehouses, a minimum of 25% of the floor live load shall be included.
- In areas subjected to flat roof snow loading greater than 30 psf, 20% of the snow load shall be included in the design regardless of actual roof slope.
- In buildings with permanent equipment, the weight of such equipment shall be included as part of the total dead load (W).

32.2.4.2 Seismic Base Shear

The International Building Code equation for calculating the total design lateral force at the base of a building in a given direction is as follows:

$$V = C_s W \quad (32.1)$$

The seismic response coefficient (C_s) is determined by:

$$C_s = \frac{S_{DS}}{\left(\frac{R}{I}\right)} \quad (32.2)$$

The value of C_s need not exceed the following:

$$C_s = \frac{S_{D1}}{T \left(\frac{R}{I}\right)} \text{ for } T \leq T_L \quad (32.3a)$$

$$C_s = \frac{S_{D1} T_L}{T^2 \left(\frac{R}{I}\right)} \text{ for } T > T_L \quad (32.3b)$$

TABLE 32.15 Values of Approximate Period Parameters C_t and x

Structure Type	C_t^a	x
Moment-resisting frame systems in which the frames resist 100% of the required seismic force and are not enclosed or adjoined by components that are more rigid and will prevent the frames from deflecting where subjected to seismic forces:		
Steel moment-resisting frames	0.028 (0.0724)	0.8
Concrete moment-resisting frames	0.016 (0.0466)	0.9
Eccentrically braced steel frames	0.03 (0.0731)	0.75
All other structural systems	0.02 (0.0488)	0.75

^a Metric equivalents are shown in parentheses.

Source: ASCE, *Minimum Design Loads for Buildings and Other Structures*, ASCE 7-05, American Society of Civil Engineers, Reston, VA, 2005. With permission.

In addition, for structures located where S_1 is greater than or equal to 0.6g, C_s shall not be less than:

$$C_s = \frac{0.5S_1}{\left(\frac{R}{I}\right)} \quad (32.3c)$$

where:

C_s = seismic response coefficient.

W = total seismic dead load of the system.

I = importance factor in Table 32.7.

R = response modification coefficient per Table 32.10.

T = fundamental period of vibration of the building.

T_L = long-period transition point.

V = total design lateral force or shear at the base.

S_{DS} = design, 5% damped, spectral response acceleration at short periods of vibration.

S_{D1} = design, 5% damped, spectral response acceleration at a period of 1 second.

S_1 = mapped MCE, 5% damped, spectral response acceleration at a period of 1 second.

The fundamental period of the structure (T) shall be determined using the structural properties and deformation characteristics of the resisting elements in a properly substantiated analysis. As an alternative to performing an analysis to determine the fundamental period (T), it is permitted to use the approximate building period (T_a). For all buildings, the value T_a may be approximated from the following formula:

$$T_a = C_t h_n^x \quad (32.4)$$

where h_n is the height in feet above the base to the highest level of the structure, and the numerical coefficients C_t and x are determined from Table 32.15.

The fundamental period (T) calculated by methods other than the approximate method shall not exceed an upper limit as determined from:

$$T \leq C_u T_a \quad (32.5)$$

where C_u is determined from Table 32.16.

Alternatively, the approximate period may be determined from the following equations when the structure does not exceed 12 stories in height and consists entirely of concrete or steel moment resisting frames with a story height of at least 10 feet:

$$T_a = 0.1N \quad (32.6)$$

where N = number of stories.

TABLE 32.16 Coefficient for Upper Limit on Calculated Period

Design Spectral Response Acceleration Parameter at 1 Second (S_{D1})	Coefficient C_u
0.4	1.4
0.3	1.4
0.2	1.5
0.15	1.6
≤ 0.1	1.7

Source: ASCE, *Minimum Design Loads for Buildings and Other Structures*, ASCE 7-05, American Society of Civil Engineers, Reston, VA, 2005. With permission.

For concrete or masonry shear-wall structures, the approximate period (T_a) may be determined from the following formula:

$$T_a = \frac{0.0019}{\sqrt{C_w}} h_n \quad (32.7)$$

where h_n is defined in the proceeding text, and C_w is calculated from the following formula:

$$C_w = \frac{100}{A_B} \sum_{i=1}^x \left(\frac{h_n}{h_i} \right)^2 \left[\frac{A_i}{1 + 0.83 \left(\frac{h_i}{D_i} \right)^2} \right] \quad (32.8)$$

where:

A_B = area of base of structure (ft²).

A_i = web area of shear wall i (ft²).

D_i = length of shear wall i (ft).

h_i = height of shear wall i (ft).

x = number of shear walls in the building effective in resisting lateral forces in the direction under consideration.

32.2.4.3 Vertical Distribution of Force

The total seismic force shall be distributed to each level of the structure in accordance with the following:

$$F_x = C_{vx} V \quad (32.9)$$

and

$$C_{vx} = \frac{w_x h_x^k}{\sum_{i=1}^n w_i h_i^k} \quad (32.10)$$

where:

C_{vx} = vertical distribution factor.

V = total design lateral force at the base of the structure (kips or kN).

w_p, w_x = the portion of the total effective seismic weight (W) located or assigned to level i or x .

h_p, h_x = the height (ft or m) from the base of the structure to level i or x .

k = an exponent related to the structure period as follows: (1) when $T < 0.5$ seconds, $k = 1$, and (2) when $T \geq 2.5$ seconds, $k = 2$; for structures having a period between 0.5 and 2.5 sec, k shall be taken equal to 2 or shall be determined by linear interpolation between 1 and 2.

TABLE 32.17 Allowable Story Drift (Δ_a)

Structure	Occupancy Category		
	I or II	III	IV
Structures, other than masonry shear walls structures, 4 stories or less with interior walls, partitions, ceilings and exterior wall systems that have been designed to accommodate the story drifts.	$0.25h_{sx}^a$	$0.020h_{sx}$	$0.015h_{sx}$
Masonry cantilever shear wall structures ^b	$0.010h_{sx}$	$0.010h_{sx}$	$0.010h_{sx}$
Other masonry shear wall structures	$0.007h_{sx}$	$0.007h_{sx}$	$0.007h_{sx}$
All other structures	$0.020h_{sx}$	$0.015h_{sx}$	$0.010h_{sx}$

^a There shall be no drift limit for single-story structures with interior walls, partitions, ceilings, and exterior wall systems that have been designed to accommodate the story drifts. The structure separation requirement of ASCE 7-05 Section 12.12.3 is not waived.

^b Structure in which the basic structural system consists of masonry shear walls designed as vertical elements cantilevered from their base or foundation support which are so constructed that moment transfer between shear walls (coupling) is negligible.

Note: h_{sx} is the story height below level x . For seismic-force-resisting systems comprised solely of moment frames in Seismic Design Categories D, E, and F, the allowable story drift shall comply with the requirements of ASCE 7-05, Section 12.12.1.1.

Source: ASCE, *Minimum Design Loads for Buildings and Other Structures*, ASCE 7-05, American Society of Civil Engineers, Reston, VA, 2005. With permission.

32.2.4.4 Horizontal Distribution of Shear and Horizontal Torsional Moments

The seismic design story shear (V_x , the sum of the forces F_i above that story) in any story shall be distributed to the various elements of the vertical lateral-force-resisting system in proportion to their rigidities, considering the rigidity of the diaphragm. Furthermore, the IBC and ASCE 7-05 require that provisions be made for the increased shears resulting from horizontal torsion where diaphragms are not flexible. To account for the uncertainties in load locations, the IBC and ASCE 7-05 further require that the mass at each level be assumed to be displaced from the calculated center of mass in each direction a distance equal to 5% of the building dimension at that level perpendicular to the direction of the force under consideration. This is often referred to as the *accidental torsion*. The torsional design moment at a given story is the moment resulting from the combination of this accidental torsional moment and the inherent torsional moment between the applied design lateral forces and the center of rigidity of the vertical lateral-force-resisting elements in that story (see Figure 32.5). When seismic forces are applied concurrently in two orthogonal directions, the required 5% displacement of the center of mass need not be applied in both orthogonal directions at the same time but shall be applied in the direction that produces the greater effect.

32.2.4.5 Story Drift Determination and Limitation

The IBC and ASCE 7-05 define *story drift* as the relative displacement between adjacent stories (above or below) due to the design lateral forces. The design story drift is computed as the difference of the deflections at the center of mass at the top and bottom of the story under consideration. ASCE 7-05 further expands on the requirements for calculating story drift by stating that, for structures with significant torsional deflections, the maximum story drift must include torsional effects. For structures assigned to Seismic Design Categories C, D, E, or F having horizontal irregularities of Type 1a or Type 1b, the design story drift (Δ) shall be computed as the largest difference of the deflections along any of the edges of the structure at the top and bottom of the story under consideration. The design story drift (Δ) shall not exceed the allowable story drift (Δ_a) determined from Table 32.17.

The deflections used to determine the design story drift shall be determined from the following equation:

$$\delta_x = \frac{C_d \delta_{xe}}{I} \quad (32.11)$$

where:

C_d = the deflection amplification factor in Table 32.10.

δ_{xe} = the deflection determined by elastic analysis without the upper limit on the fundamental period ($C_u T_a$).

I = the importance factor determined from Table 32.7.

Past codes, such as the Uniform Building Code, did not elaborate on how story drift is determined from analysis results. As a result, it was often assumed that the drift should be calculated at the structure extremities as is now required by ASCE 7-05 only in certain seismic design categories and when torsional irregularities exist. This can have a liberalizing effect on drift requirements of moment frame structures that are often governed by drift. Whereas these requirements seem to loosen drift requirements that would impact moment frame structures, a limitation has been put into place on the allowable story drift requiring that the design story drift not exceed Δ_u/ρ for structures assigned to Seismic Design Categories D, E, or F.

32.2.4.6 P-Delta Effects

P-delta effects on story shears and moments, the resulting member forces and moments, and the story drifts induced by these effects are not required to be considered where the stability coefficient θ , as determined by the following equation, is less than or equal to 0.10:

$$\theta = \frac{P_x \Delta}{V_x h_{sx} C_d} \quad (32.12)$$

where:

P_x = total vertical design load at and above level x (kips or kN); when computing P_x , no individual load factor need exceed 1.0.

Δ = design story drift occurring simultaneously with V_x (in. or mm).

V_x = seismic shear force acting between levels x and $x - 1$ (kips or kN).

h_{sx} = story height below level x (in. or mm).

C_d = deflection amplification factor in Table 32.10.

The stability coefficient θ shall not exceed θ_{\max} determined as follows:

$$\theta_{\max} = \frac{0.5}{\beta C_d} \leq 0.25 \quad (32.13)$$

where β is the ratio of shear demand to shear capacity for the story between levels x and $x - 1$. This ratio may conservatively be taken equal to 1.0.

When $0.10 < \theta \leq \theta_{\max}$, the incremental factor related to P-delta effects on displacement and member forces shall be determined by rational analysis. As an alternative, it is permitted to multiply displacements and member forces by $1.0/(1 - \theta)$. When $\theta > \theta_{\max}$, the structure is potentially unstable and shall be redesigned. Where P-delta effects are included in an automated analysis, Equation 32.13 will still be satisfied; however, the value of θ computed from Equation 32.12 using the results of the P-delta analysis is permitted to be divided by $(1 + \theta)$ before checking Equation 32.13.

32.2.4.7 Deformation Compatibility

For structures assigned to Seismic Design Categories D, E, or F, all framing elements not required by design to be part of the lateral-force-resisting system must be investigated and shown to be adequate for vertical-load-carrying capacity when subjected to the design story drift (Δ) resulting from the required design lateral force. Reinforced concrete frame members not designed as part of the lateral-force-resisting system shall comply with Section 21.9 of ACI 318.

32.2.5 Modal Response Spectrum Analysis

ASCE 7-05 sets some rather general requirements regarding modal response spectrum analysis (dynamic analysis). The following is a summary of the requirements:

- The analysis shall include a sufficient number of natural modes of vibration for the structure such that the modal mass participation in each direction is at least 90% of the actual mass.
- The design forces shall be determined using the properties of each mode and the response spectrum defined in either Section 32.2.1.5 or Section 21.2 of ASCE 7-05 divided by R/I . When calculating displacement and drift, values shall be multiplied by C_d/I .
- The value for each response parameter shall be combined using either the square root sum of the squares (SRSS) method or the complete quadratic combination (CQC) method, in accordance with ASCE 4.
- A base shear shall be calculated in each of the two orthogonal directions using the equivalent lateral force procedure of Section 32.2.4. When the fundamental period of vibration exceeds the cap $C_u T_a$, then $C_u T_a$ shall be used in lieu of T in that direction.
- Where the combined response for the modal base shear (V_l) is less than 85% of the calculated base shear (V) using the equivalent lateral force procedure, the forces, but not the drifts, shall be multiplied by $0.85V/V_l$.
- The horizontal distribution of shear shall be in accordance with the horizontal distribution requirements of the equivalent lateral force procedure except that the amplification of the torsional effects required when a horizontal irregularity Type 1a or Type 1b exists is not required when accidental torsional effects are included in the dynamic analysis model.
- P-delta effects are determined in accordance with the same requirements as the equivalent lateral force procedure, as well as the story shears and story drifts.
- A soil structure interaction reduction is permitted where determined using ASCE 7-05, Chapter 19.

As can be seen from the above requirements, even though a separate method of analysis is being employed, the requirements of the equivalent lateral force procedure still play a large role in the modal response spectrum analysis.

32.2.6 Seismic Load Combinations

The basic load combinations for strength design are as follows:

$$(1.2 + 0.2S_{DS})D + \rho Q_E + L + 0.2S \quad (32.14)$$

$$(0.9 - 0.2S_{DS})D + \rho Q_E + 1.6H \quad (32.15)$$

The basic load combinations for strength design with the overstrength factor (Ω_O) are as follows:

$$(1.2 + 0.2S_{DS})D + \Omega_O Q_E + L + 0.2S \quad (32.16)$$

$$(0.9 - 0.2S_{DS})D + \Omega_O Q_E + 1.6H \quad (32.17)$$

where:

D = dead loads or related internal moments and forces.

L = live loads or related internal moments and forces.

Q_E = effects of horizontal seismic forces from V or F_p .

ρ = redundancy factor from Section 32.2.3.10.

S_{DS} = design spectral acceleration parameter defined in Section 32.2.1.4.

H = load due to earth pressure, ground water pressure, or pressure of bulk materials.

S = snow load.

Ω_O = overstrength factor.

The load factor applied to the live load in the above load combinations is permitted to equal 0.5 for all occupancies where the live load is less than or equal to 100 psf with the exception of garages or areas of public assembly. The load factor on H in the above load combinations shall be set equal to zero if the structural action due to H counteracts that due to E . Where lateral earth pressure provides resistance to structural actions other than seismic, it shall not be included in H but shall be included in the design resistance. When utilizing the load combinations including the overstrength factor, the required design strength for an element need not exceed the maximum force that can be developed in the element as determined by rational, plastic mechanism analysis, or nonlinear response analysis utilizing realistic expected values of material strengths.

32.2.7 Diaphragms, Chords, and Collectors

Floor and roof diaphragms are required to be designed to resist the forces determined in the following formula:

$$F_{px} = \frac{\sum_{i=x}^n F_i}{\sum_{i=x}^n w_i} w_{px} \quad (32.18)$$

The force (F_{px}) determined in the above formula need not exceed $0.4S_{DS}Iw_{px}$ but shall not be less than $0.2S_{DS}Iw_{px}$. For structures assigned to Seismic Design Categories D, E, and F, redundancy factor ρ shall be used in the diaphragm design. For inertial forces calculated in accordance with Equation 32.18, the redundancy factor shall equal 1.0. For transfer forces, the redundancy factor shall be the same as that used for the structure. For structures assigned to Seismic Design Categories D, E, or F and having a horizontal structural irregularity of Types 1a, 1b, 2, 3, or 4 from Table 32.11 or a vertical irregularity of Type 4 from Table 32.12, the design forces determined from Section 32.2.2.2 shall be increased 25% for connections of diaphragms to vertical elements and to collectors. Collectors and their connections shall be designed for these increased forces unless they are designed for the load combinations that include the overstrength factor.

32.2.8 Building Separation

All structures have to be separated from adjoining structures a distance sufficient to avoid damaging contact under total deflection δ_x . ASCE 7-05 does not further expand on what is considered a sufficient distance; however, past codes allowed the separation to be based on the square root sum of the squares of the estimated maximum seismic displacement due to code-specified seismic forces of the two structures. The separation was calculated as $\delta_s = \sqrt{\delta_{x1}^2 + \delta_{x2}^2}$, where δ_{x1} and δ_{x2} are the displacement of adjacent buildings and δ_s is the calculated required building separation.

32.2.9 Anchorage of Concrete or Masonry Walls

Concrete or masonry walls shall be provided with a positive direct connection to all floors and roofs that provide them lateral support. Such connections shall be capable of resisting the horizontal forces induced by the seismic excitement and as specified in the code. ASCE 7-05, Section 12.11, should be consulted for further information.

32.2.10 Material-Specific Design and Detailing Requirements

The IBC and ASCE 7-05 make a series of modifications to ACI 318. The IBC in turn makes a series of modifications to both ASCE 7-05 and ACI 318 in Chapters 16 and 19. ASCE 7-05 lists the required modification as part of Chapter 14.

32.2.11 Foundation Design

The foundation shall be designed to resist the forces developed and accommodate the movements imparted to the structure by the design ground motions. Importantly, overturning effects at the soil–foundation interface are permitted to be reduced by 25% for foundations of structures that are designed in accordance with the equivalent lateral force analysis procedure provided the structure is not an inverted pendulum or cantilevered column type structure. Overturning effects at the soil–foundation interface are permitted to be reduced by 10% for foundation of structures designed in accordance with the modal response spectrum analysis procedure. Refer to ASCE 7-05, Section 12.13, for additional foundation design requirements.

32.3 Design and Construction of Concrete and Masonry Buildings

32.3.1 Preface

This section is intended to serve as a guide to engineers in the design of reinforced-concrete and masonry buildings to resist earthquake forces in conformance with the 2006 IBC and ASCE 7-05 (refer to Section 32.2). The lateral-load-resisting system, including horizontal diaphragms, is addressed. Please note that term definitions, notations, and symbols used in this chapter are provided in the 2006 IBC and ASCE 7-05.

32.3.2 Concrete Buildings

32.3.2.1 Introduction

As discussed in Section 32.2, reinforced-concrete buildings in general are designed to have adequate strength to resist the equivalent static lateral load and appropriate ductility to allow the structure to displace as a result of dynamic earthquake excitement. The building strength is achieved by selecting the appropriate member sizes, concrete strength, proper placement, and adequate size of reinforcing steel so the nominal capacity decreased by a reduction factor of each member meets or exceeds the ultimate demands. Ductility is achieved by providing confinement to the concrete section at critical locations by introducing closely spaced and appropriately anchored bars transversely to the longitudinal reinforcement in beams, columns, and boundary members such as at the ends of a shear wall (see Figure 32.9).

When designing a building to resist the seismic forces obtained in Section 32.2, the engineer would go through selection of the lateral-force-resisting system. This section addresses shear walls and special moment-resisting frames, as they are primarily used in Seismic Design Categories D, E, and F. The decision of whether to choose shear walls or moment frames or a combination of the two depends on the architectural layout of the structure. The structural engineer's role in most cases is limited to locating and sizing the lateral resisting elements. The following steps are then followed in the lateral design of the structure:

- Select the lateral-force-resisting system.
- Calculate the building weight and base shear (see Section 32.2).
- Distribute lateral load to each floor and calculate the story shear (see Section 32.2).
- Distribute story shear to the various lateral-force-resisting elements at each floor based on member stiffness (see Section 32.2.4.4).
- Design and detail lateral-force-resisting components (shear wall or moment frame) for the applied forces.
- Design and detail diaphragms to transfer story shear into shear walls or moment frames.

32.3.2.2 Horizontal Distribution of Shear and Torsional Moments

The following discussion addresses the distribution of shear and torsional moments on the basis that the lateral-force-resisting system consists of shear walls. The same discussion also applies to buildings

FIGURE 32.4 Schematic center of mass in shear wall.

FIGURE 32.5 Cantilever shear-wall deflection.

with moment frames or combination of shear walls and moment frames. The center of mass of the floor is first calculated as follows:

$$X_m = \frac{\sum wx}{\sum w} \quad (32.19)$$

$$Y_m = \frac{\sum wy}{\sum w} \quad (32.20)$$

Figure 32.4 serves as a good illustration for the above formulas. Next, the rigidity of each wall is calculated. The deflection at the top of the wall is calculated based on the following formula:

$$\Delta_T = \Delta_F + \Delta_S = \frac{Ph^3}{3E_G I} + \frac{1.2Ph}{AE_G} \quad (32.21)$$

where r is the rigidity or stiffness of the wall panel equal to $1/\text{deflection}$ (see Figure 32.4, Figure 32.5, and Figure 32.6). The center of rigidity of the floor is then calculated as follows:

$$\bar{x}_r = \frac{\sum r_x x}{\sum r_y} \quad (32.22)$$

$$\bar{y}_r = \frac{\sum r_x y}{\sum r_x} \quad (32.23)$$

Refer to Figure 32.7 for the shear distribution formulation.

FIGURE 32.6 Schematic center of rigidity in a shear wall.

FIGURE 32.7 Shear distribution formulation.

32.3.2.3 Design of Vertical Lateral-Force-Resisting Elements

This section illustrates the design and reinforcement requirements for shear walls and moment-resisting frames through practical examples.

Example 32.1. Shear-Wall Design and Reinforcement Requirements

(See Figure 32.8.) The given values are as follows:

- $f'_c = 4000$ psi.
- t (wall thickness) = 12 in.

FIGURE 32.8 Typical shear wall elevation.

$V_u = 980$ kips = shear force.

$M_u = 73,500$ kip-ft = overturning moment.

$P_u = 2800$ kips = total load on wall, includes wall weight.

$S_{DS} = 1.1$ (site class D).

$L = 53$ ft.

$H = 75$ ft.

Note that walls with a height-to-width ratio (H/W) greater than 2.0 behave primarily as bending members, whereas walls with H/W below 2.0 resist lateral forces in a predominantly truss-type behavior. The maximum shear stress in walls is limited to $2\sqrt{f'_c}$.

- The vertical steel in the wall is required to equal the horizontal steel.
- At least two curtains of reinforcement shall be used in a wall if the in-plane factored shear force assigned to the wall exceeds $2A_{cv}\sqrt{f'_c}$. A_{cv} is the cross-sectional area bounded by the wall length parallel to the direction of the shear force and the wall thickness.

Check number of curtains required:

$$2A_{cv}\sqrt{f'_c} = \left(2 \times 12 \times (53 \times 12) \sqrt{4000}\right) / 1000 = 965.4 \text{ kips}$$

$$V_u = 980 \text{ kips}$$

$$V_u > 2A_{cv}\sqrt{f'_c} \therefore \text{two curtains of reinforcement are required}$$

- Required vertical and horizontal wall reinforcement:

$$\text{Minimum rebar ratio, } \rho_v = 0.0025$$

$$\text{Area of steel in each, } \rho_v A_{cv} = 0.0025 \times 12 \text{ in.} \times 12 \text{ in.} = 0.36 \text{ in.}^2/\text{ft}$$

- Try #5 bars in each direction at each face at 18 in. on-center $\leq S_{\max} = 18$ in.

$$A_m = 2 \times 0.31 \times 12 / 18 = 0.413 \text{ in.}^2$$

$$h_w / l_w = 75 \text{ ft} / 53 \text{ ft.} = 1.42 < 2$$

$$V_n = A_{cv} (\alpha_c \sqrt{f'_c} + \rho_n f_y)$$

$$A_{cv} = 12 \times (53 \times 12) = 7632 \text{ in.}^2$$

$$\alpha_c = 3.0 \quad (\alpha_c \text{ varies linearly from 3.0 for } h_w / l_w = 1.5 \text{ to 2.0 for } h_w / l_w = 2.0)$$

$$\rho_n = 2 \times 0.31 / (12 \times 18) = 0.0029$$

$$\phi = 0.6$$

- Check:

$$V_n \leq 10 A_{cv} \sqrt{f'_c}.$$

$$V_n = \frac{7632}{1000} (3 \sqrt{4000} + 0.0029 \times 60,000) = 2776 \text{ kips}$$

$$10 A_{cv} \sqrt{f'_c} = 10 \times 7632 \times \sqrt{4000} / 1000 = 4827 \text{ kips} \quad \therefore V_n < 10 A_{cv} \sqrt{f'_c} \quad (\text{OK})$$

Boundary member requirement: Boundary members shall be provided where the maximum compressive and extreme-fiber stress under factored forces exceeds $0.2f'_c$.

- Gross section properties:

$$l = 53 \text{ ft, } t = 12 \text{ in.}$$

$$A_{cv} = 53 \times 12 \times 12 = 7632 \text{ in.}^2$$

$$I_y = 12 \times (53 \times 12)^3 / 12 = 257,259,456 \text{ in.}^4$$

$$f_c = P_u / A_g + M_u (l_w / 2) / I_y$$

$$P_u = 2800 \text{ kips}$$

$$M_u = 73,500 \text{ kip-ft}$$

$$f_c = \frac{2800}{7632} + \frac{73,500 \times 12 \times 53 \times 12 / 2}{257,259,456} = 1.46 \text{ ksi}$$

$$0.2f_c = 0.2 \times 4 = 0.8 \text{ ksi} < 1.46 \text{ ksi} \quad \therefore \text{provide boundary member}$$

- Check axial capacity of 36×36 -in. boundary member with 12 #11:

$$A_y = 36 \times 36 = 1296 \text{ in.}^2$$

$$A_{st} = 12 \times 1.56 = 18.72 \text{ in.}^2$$

$$\rho_g = 18.72 / 1296 = 0.0144$$

$$\rho_{\min} = 0.01 < \rho_g < \rho_{\max} = 0.06 \quad (\text{OK})$$

$$P_u = \phi P_n = 0.6 [0.85 f'_c (A_y - A_{st}) + f_y A_{st}] = 3279 \text{ kips} > P_u \quad (\text{OK})$$

- Use 36×36 -in. boundary members with 12 #11.

- Check boundary reinforcement for tension load for load combination:

$$T_u = (0.9 - 0.2S_{DS})D \pm E$$

$$P_D = 1400 \text{ kips}$$

$$T_u = 73,500 / (53 - 3) - (0.9 - 0.2 \times 1.1) \times 1400 \times 0.5 = 994 \text{ kips}$$

$$A_s = T_u / \phi f_y = 994 / (0.9 \times 60) = 18.41 \text{ in.}^2 \quad (\text{OK})$$

Other requirements: (1) Required cross-sectional area of confinement reinforcement should be in accordance with ACI 318-05; see Nawy (2008) for a detailed example. (2) All continuous reinforcement in shear walls must be anchored or spliced as required by IBC and ACI.

32.3.3 Design of Masonry Buildings

32.3.3.1 Introduction

The majority of construction in the masonry industry involves smaller buildings, and these are often designed with the code-equivalent static loads. It is the intent of this section to briefly demonstrate how the building must be designed to resist these equivalent static lateral forces. Again, for computational convenience, the effects of ground motion are considered as if the motion acts only in one direction parallel to the perpendicular axes of the building. Several different types of structural systems are used to resist the static lateral forces and carry them into the foundation. Such systems include shear walls, braced frames, and moment-resisting space frames. Because it has not been possible, so far, to feasibly construct masonry moment-resisting frames, this chapter is limited to the discussion of concrete masonry shear walls.

32.3.3.2 General Behavior of Box Buildings

A box system does not have an independent vertical-load-carrying frame but rather depends on the walls not only to carry the vertical loads but also to provide the necessary lateral stability. Walls that are perpendicular to the assumed direction of the ground motion must span vertically between the floor diaphragms. The inertial effect of one half the wall height, both above and below the floor level in question, is considered to be transferred to that floor diaphragm. In addition, the inertial effect of the diaphragm dead load itself must be taken by the diaphragm. The diaphragm essentially behaves as a horizontal plate girder, wherein the diaphragm boundary members serve as the girder flanges and the floor functions as the web. The diaphragm therefore spans between the supporting shear walls. Through the diaphragm-to-wall connection, the total horizontal shear is transferred directly to the shear wall. Depending on the rigidity of the diaphragm, this lateral shear transfer to any shear wall may be based on the adjacent tributary area or the relative rigidities of the various shear walls. Where rigid diaphragms such as reinforced or post-tensioned concrete floor slabs are used, each wall experiences a torsional shear in addition to the direct shear when the building center of gravity and the center of rigidity of the vertical lateral-force-resisting elements do not coincide. The total direct lateral shear and the torsional shear are combined so the sum becomes the total UBC-design force imposed upon the shear wall. Figure 32.7 provides an illustration of the total shear force, lateral load combination.

32.3.3.3 Shear Walls

32.3.3.3.1 Shear-Wall Design

Roof and floor seismic forces may be carried down to the building foundation by the strength and rigidity of the building walls in a bearing wall system or building frame system. Such walls are called *shear walls*. In tall buildings, design of the shear walls is generally governed by flexure, whereas in low buildings shear is often the governing criteria. The shear wall is basically a cantilever member with the shear force resisted by the combined shear strength of the masonry and the horizontal rebar in the wall, while the vertical

FIGURE 32.9 Typical placement of reinforcement in masonry shear wall.

boundaries (end reinforcement) provide the capacity to resist tension and compression caused by the bending moment and axial forces on the wall. A shear wall by definition is a wall resisting in-plane horizontal shear forces. In addition to horizontal force, the wall is investigated for the effects of the vertical loads it is subjected to. Example 32.2 provides a good illustration for the design of a concrete masonry wall subjected to both gravity and seismic forces.

32.3.3.3.2 Shear-Wall Detailing

For a masonry wall to function properly as a shear wall, it must be capable of resisting the diagonal tensile forces imposed by the design shear forces and the vertical compressive or tensile stresses caused by the overturning moment due the same design shear forces. A typical detail for placing reinforcing steel in a masonry wall is shown in Figure 32.9. The horizontal rebar is anchored with a 90° standard hook to ensure that the bar can be fully developed in tension. Also shown in Figure 32.9 is the end reinforcement for a four-bar condition to resist tensile forces. Figure 32.8 shows an elevation of the same wall with the wall-to-floor and wall-to-footing connections properly shown. It is important to note that the designer must take into account the limited amount of space in the cells when specifying the bar size and spacing so the placement of reinforcement does not become impossible.

Example 32.2. Masonry Shear-Wall Design

The given values are as follows:

Masonry, CMU $f'_m = 1500$ psi

Grout, type M, 2000 psi

Steel, Gr 60

Special inspection required

Wall length, 31 ft

Wall thickness, 12 in

Wall height, 12 ft

Shear force, 203.45 kips

Moment, 3051.7 kip-ft

Axial loading, 95.00 kips

The following items are required:

Stress check

Reinforcement requirements

The following calculations are necessary (calculations are based on design UBC 1991):

$$E_m = 750 \times 1500 = 1125 \text{ ksi.}$$

$$E_s = 29,000 \text{ ksi.}$$

$$\text{Ratio of moduli} = 29,000/1125 = 25.78.$$

$$\text{Allowable steel stress } (F_s) = 24,000 \text{ psi.}$$

$$\text{Increase for seismic design } (1.33F_s) = 1.33 \times 24,000 = 31,920 \text{ psi.}$$

$$\text{Allowable bending stress } (F_b) = 0.33f'_m = 0.33 \times 1500 = 495 \text{ psi.}$$

$$\text{Increase for seismic design } (1.33F_b) = 658.35 \text{ psi.}$$

$$\text{Allowable axial stress } (F_a/R) = 0.2f'_m = 0.2 \times 1500 = 300 \text{ psi.}$$

$$\text{Increase for seismic design} = 399 \text{ psi.}$$

The design for bending and axial load is as follows:

$$R = \left[1 - \left(h / 42t \right)^3 \right]$$

$$h = 12 \times 12 = 144 \text{ in.}$$

$$t = 11.625 \text{ for 12 in./in. CMU}$$

$$R = 1 - \left(\frac{144}{42 \times 11.625} \right)^3 = 0.97$$

$$f_a = \frac{P}{A} = \frac{95 \times 1000}{31 \times 12 \times 11.625} \cong 22 \text{ psi}$$

$$\text{Allowable axial stress } (F_a) = 399 \times 0.97 = 387 \text{ psi.}$$

$$\text{Axial stress ratio } (f_a/F_a) = 21.97/387 = 0.057.$$

$$\frac{f_a}{F_a} + \frac{f_b}{F_b} = 1$$

$$\text{Hence, } f_b/F_b = 1 - 0.057 = 0.943.$$

Assume that masonry stress governs and check for steel stress. If steel stress as calculated exceeds its allowable stress, then discard the assumption and proceed by assuming steel reaches its maximum allowable value first.

(I) Masonry stress governs.

$$f_b = 0.943 \times 658.35 = 621 \text{ psi}$$

$$jk = \frac{2M}{f_b b d^2} = \frac{2 \times 3051.70 \times 12,000}{620.98 \times 11.625 \times 354^2} = 0.081$$

where $d = 12 \times 3 \text{ ft} - 18 \text{ in.} = 354 \text{ in.}$

$$k^2 - 3k + 3jk = 0$$

$$k^2 - 3k + 3 \times 0.081 = 0$$

$$k = 0.0833$$

$$f_s n f_b \left(\frac{1-k}{k} \right) = 25.78 \times 620.98 \left(\frac{1-0.0833}{0.0833} \right) = 176,128 \text{ psi} > 31,920 \text{ psi} \therefore \text{N.G.}$$

(II) Steel stress governs.

$$A_s = \frac{M}{f_s j d} = \frac{3051 \times 12,000}{31,920 \times 0.972 \times 354} = 3.33 \text{ in.}^2 = \text{area of jamb reinforcement}$$

where $j = jk/k = 0.81/0.0833 = 0.972$.

Check compressive stress in the masonry:

$$\rho = A_s / bd = 3.33 / 11.625 \times 354 = 8.09 \times 10^{-4}$$

$$k = \sqrt{2\rho n + (\rho n^2)} - \rho n = \sqrt{2 \times 8.09 \times 10^{-4} \times 25.78 + (25.78 \times 8.09 \times 10^{-4})^2} - 8.09 \times 10^{-4} \times 25.78 = 0.23$$

$$j = 1 - k / 3 = 1 - 0.23 / 3 = 0.923$$

$$f_b = \frac{2M}{j k b d^2} = \frac{2 \times 3051.70 \times 12,000}{0.923 \times 0.162 \times 11.625 \times 354^2} = 336 \text{ psi} < 658.35 \text{ psi} \quad \therefore \text{OK}$$

The bending stress ratio is:

$$\frac{f_b}{F_b} = \frac{336}{658.35} = 0.51 \quad \therefore \text{OK}$$

The combined bending and axial stress ratio is:

$$\frac{f_a}{F_a} + \frac{f_b}{F_b} = 0.06 + 0.51 = 0.57 < 1 \quad \therefore \text{OK}$$

Check shear stresses:

$$\frac{M}{Vd} = \frac{3051.7}{203.45 \times (0.8 \times 31)} = 0.6 < 1 \quad \therefore \text{OK}$$

where $d \cong 0.8 \times 31$.

$$\text{for } M/Vd = 1, F_v = 1.33 \times 1.5 \sqrt{1500} = 77.27 \text{ psi} < 1.33 \times 75 \text{ psi} \quad \therefore \text{OK}$$

$$\text{for } M/Vd = 0, F_v = 1.33 \times 2 \sqrt{1500} = 103.02 \text{ psi} < 1.33 \times 120 \text{ psi} \quad \therefore \text{OK}$$

The allowable ranges for design with rebar are:

$$F_v = 77.27 + (1 - 0.6)(103.02 - 77.27) = 87.33 \text{ psi}$$

Hence, the design stress is $F_v = 77.27 + (1 - 0.6)(103.02 - 77.27) = 87.33 \text{ psi}$, and the governing stress value is $F_v = 87.33 \text{ psi}$.

The actual stress value is:

$$F_v = \frac{V_u}{b j d} = \frac{1.5 \times 203.45 \times 1000}{11.625 \times 0.923 \times 354} = 80.34 \text{ psi}$$

The shear stress ratio is:

$$\frac{f_v}{F_v} = 80.34 / 87.33 = 0.92 \quad \therefore \text{OK}$$

Calculate the shear reinforcement:

$$\text{Horizontal, } A_s = \frac{V_u s}{f_s j d} = \frac{1.5 \times 203.45 \times 1000 \times 12}{31,920 \times 0.923 \times 345} = 0.351 \text{ in.}^2$$

$$\text{Minimum, } A_s = 0.0007 \times 11.625 \times 12 = 0.1 \text{ in.}^2 < 0.351 \text{ in.}^2 \therefore \text{OK}$$

$$\rho_n = 0.351 / 11.625 \times 12 = 0.00252 > 0.002$$

Hence, minimum ρ_u governs: $A_v = 0.0007 \times 11.625 \times 12 = 0.1 \text{ in.}^2/\text{ft.}$

32.3.4 Shear-Wall Foundation Analysis and Design

32.3.4.1 Background

The analysis and design presented herein pertain to the sizing of the shear-wall foundations and determination of their structural adequacy. The algorithm adopted is aimed at obtaining economical foundation dimensions with due consideration of all the major parameters such as the actions from the shear wall, the permissible soil pressure, concrete strength, the shear-wall foundation, and grade beam dimensions. The analysis and design are directed toward the seismic-loading case only. The adequacy of the foundation under gravity loading is to be established separately. Under normal conditions, however, the size and reinforcement of a shear-wall foundation is governed by the seismic case. The gravity case check will be conducted for unusual cases and dimensions. The analysis is based on the limit design concept. A probable failure mechanism is assumed (refer to the free body diagrams in Figure 32.10). By satisfying the requirements of statics, the actions (shears and moments) at critical sections are determined, and the cross-sectional area and reinforcement at such sections are evaluated. The failure mechanism selected may not be the optimum for all cases, but it is consistently conservative.

The soil pressure is checked by determining the soil stress ratio (SSR). This is the ratio of the calculated unfactored soil pressure to the permissible soil pressure. SSR is to be kept less than 1. The analysis assumes that the foundation is tied to the remainder of the structure through grade beams. If the foundation by itself can resist the applied loading without need for grade beams, the calculated shear transfer (parameter G) between the foundation and the grade beam will become zero or negative. If a shear transfer between the foundation and the assumed grade beams results, the analysis and design must be followed by a grade beam design to ensure that the resulting shear (G) is satisfactorily dissipated into the grade beam and the other structural elements.

The applied vertical loading (P), the seismic moment (M), and the shear (V) from the shear wall are calculated elsewhere and are entered herein (see Example 32.3) as input. They act at midlength of the shear wall at the top of the foundation. This design considers the vertical loading and the moment components of the shear wall. The shear component (V) is resisted through friction at the bottom of the foundation, axial loading in the adjoining grade beams, and the connection of the foundation to the slab on grade, as well as by any passive soil pressure that may develop. In common cases, foundation and grade beam sizes, through other considerations, prove to be adequate for V ; however, for isolated foundations this may not be the case. If required, this design section is followed by a check for the shear component V .

One type of typical interior foundation is treated in Example 32.3. Numerous variations are possible depending on the existence of and location at which a grade beam ties into the foundation. The relationships developed embrace most of the common cases. If a foundation geometry does not fall within the scope of this work and cannot be modeled conservatively through the method treated herein, special analysis and design are required. In nonsymmetrical cases, different values for the shear transfer force (G) result, depending on the direction of the applied seismic-bending moment. In such conditions, the value yielding the larger shear transfer is calculated and given.

FIGURE 32.10 Shear wall foundation: (a) elevation, shear wall and footing; (b) plan; (c) free body diagram of the structural system at limit state.

32.3.4.2 Geotechnical Relationships

32.3.4.2.1 Soil Pressure

The soil pressure is:

$$s = \frac{P_d}{0.25LB} \leq 1.33SBP \quad (32.24)$$

where P_d is the total $(DL + LL)$.

32.3.4.2.2 Soil Pressure Ratio

The soil stress ratio is:

$$SSR = \frac{s}{1.33SBP} \leq 1 \quad (32.25)$$

32.3.4.2.3 Shear Transfer to Grade Beam (G)

(See Figure 32.10.) Based on the structural model adopted at the limit state, shear transfer (G) to the grade beams occurs if the shear-wall footing is not capable, through its geometry and the existing gravity loadings, to resist the overturning moment (M). The magnitude of the shear G depends also on the direction of bending moment M . The larger of the two values is considered for design:

$$G = \frac{1}{L} \left[M - 0.375PL + |0.5(e - f)| \right] \quad (32.26)$$

$$\text{Factored average soil bearing } (W) = 4P/BL \quad (32.27)$$

32.3.5 Nomenclature

- b = width of grade beam.
- B = width of foundation pad and its tips.
- d = design depth of footing.
- d_g = design depth of grade beam.
- e = distance from tip of shear wall to tip of footing at bearing end.
- f = distance from tip of shear wall to tip of footing at uplift end.
- g = distance from tip of shear wall to point of action of shear force G .
- G = factored shear force developed between the grade beam and foundation.
- h = dimensional depth of footing.
- h_g = dimensional depth of grade beam.
- j = distance from tip of shear wall to point of action of shear force G .
- k = width of footing at midlength of shear wall.
- l = length of shear wall.
- L = effective length of foundation (equal to $l + e + f$).
- M = factored moment at midlength of shear wall (equal to $M_s/0.7$).
- M_s = unfactored applied seismic moment.
- P = factored gravity load equal to $(0.9 - 0.2S_{DS})P_d$.
- P_a = unfactored gravity loading from the shear wall.
- P_d = total axial load on footing (equal to $P_a + P_f$).
- P_f = total weight of footing.
- P_L = unfactored live load from shear wall
- s = unfactored calculated soil pressure.
- SBP = allowable soil bearing pressure.
- SSR = soil stress ratio (equal to calculated/allowable).
- V = factored applied seismic shear.
- V_s = unfactored applied seismic shear.
- W = factored calculated soil pressure on soil.

Example 32.3. Shear-Wall Footing Design

(Refer to Figure 32.10 and Figure 32.11). From the soils report, $SBP = 3.0$ kips/ft². From lateral analysis, $M_s = 9800$ kip-ft, $P_a = 100$ kips, $P_L = 0$ kips, $V_s = 300$ kips, and $SDS = 1.0$. The properties are (calculations based on design IBC 2006):

$$\begin{aligned} f'_c &= 3000 \text{ psi.} \\ f_y &= 60 \text{ psi.} \end{aligned}$$

FIGURE 32.11 Reinforcement designation: (a) elevation, and (b) plan. Note: The connection between the grade beam and the foundation is modeled as hinged in the analysis. It is not necessary to design for a moment across this section.

$$e = 6 \text{ ft.}$$

$$f = 6 \text{ ft.}$$

$$l = 36 \text{ ft.}$$

$$L = l + e + f = 48 \text{ ft.}$$

The estimated weight of the footing is:

$$P_f = 60 \text{ kips}$$

$$P_d = P_a + P_f = 100 \text{ kips} + 60 \text{ kips} = 160 \text{ kips}$$

$$P = (0.9 - 0.2)(P_d - P_L)(160 \text{ kips}) = 112 \text{ kips}$$

$$M = \frac{M_s}{0.7} = \frac{9800 \text{ kip-ft}}{0.7} = 14,000 \text{ kip-ft}$$

From Equation 32.24:

$$B_{\min} = \frac{P_d}{0.25L(1.33SBP)} = \frac{160 \text{ kips}}{0.25(48 \text{ ft})(1.33 \times 3.0)} = 40.1 \text{ in.}$$

Assume $B = 48$ in.:

$$s = \frac{P_d}{0.25LB} = \frac{160 \text{ kips}}{0.25(48 \text{ ft})(4 \text{ ft})} = 3.33 \text{ kips/ft}^2$$

$$SSR = \frac{s}{1.33SBP} = \frac{3.33 \text{ kips/ft}^2}{1.33(3.0 \text{ kips/ft}^2)} = 0.833 < 1.0 \quad (\text{OK})$$

Assume $d_g = 26.5$ in.; $h_g = d_g + 3.5$ in. = 26.5 in. + 3.5 in.; therefore, $h_g = 30$ in.

From Equation 32.27:

$$W = \frac{4P}{BL} = \frac{4(112)}{(4 \text{ ft})(48 \text{ ft})} = 2.33 \text{ kips/ft}^2$$

Reinforcement requirements of foundation:

$$G = \frac{1}{L} \left[M - 0.375PL + |0.5P(e - f)| \right]$$

$$G = \frac{1}{48 \text{ ft}} \left[14,000 \text{ kip-ft} - 0.375(112 \text{ kips})(48 \text{ ft}) + 0 \right]$$

$$G = 249.67 \text{ kips}$$

See Figure 32.11a, rebar 2D 1:

$$M_u = Gf + \frac{Bfh}{12^3} \times 0.15 \frac{f}{2} = (249.67 \text{ kips})(6 \text{ ft}) + (4 \text{ ft})(6 \text{ ft})(3 \text{ ft}) \times 0.15 \text{ kcf} \times \frac{6 \text{ ft}}{2}$$

$$M_u = 1530.4 \text{ kip-ft}$$

$$A_{SREQ} = 11.68 \text{ in.}^2$$

32.4 Seismic Retrofit of Existing Buildings

32.4.1 Introduction

Historically, the seismic retrofit of existing concrete structures has been executed by introducing concrete shear walls, new steel, or concrete bracing elements or by strengthening existing lateral-force-resisting members. Recently, new methods such as base isolation and wrapping columns using steel jackets or fiber fabric with epoxy resin have been introduced. The method and the economy of the seismic retrofit depend on the characteristics of the structure. The most critical stage in the retrofit of a concrete structure is the preliminary work for the development of the retrofit scheme. During this phase, the structural components of the structure, the economy, the various retrofit schemes, the timing of the work, and the possibility of loss of occupancy are all investigated so the appropriate seismic retrofit option may be chosen.

32.4.2 Structure Weakness

Concrete structures observed to suffer the most in the aftermath of major seismic events have exhibited one or more of the following deficiencies:

- Suspect load path or, as is occasionally the case, interrupted load path
- Lack of compatibility between the vertical elements in the structure
- An inadequate lateral-load-resisting system

For a structure to respond adequately to the applied seismic loads, there must exist a continuous and adequate load path from the point of application of the seismic force to the foundation of the structure. Inadequately designed or detailed connections along the load path can and will lead to local or overall failure, regardless of how well the various components of the lateral-force-resisting system are designed and detailed. The issue of deformation compatibility can be seen very clearly in a structure with flexible vertical lateral-force-resisting elements such as moment-resisting frames. Such frames experience significant horizontal displacements. It is this earthquake-imposed deformation that can cause some or all of the lateral and vertical carrying systems to fail if they do not have the ability to allow such movement. As building codes evolve on the basis of lessons learned from various seismic events worldwide, higher design loads with a more advanced level of detailing for ductile behavior (not widely practiced before) are demanded. Structures designed according to codes as late as 1967 may be inadequate, based on current standards. Efforts to retrofit such structures to meet current governing codes can be very extensive. Toward achieving our present objectives of ensuring life safety during major seismic events and minimal structural damage during frequently occurring earthquakes, the next two sections address two critical objectives in the seismic retrofit process.

32.4.3 Creation of Adequate Load Path

The structural engineer chooses the load path to support the lateral load from the point of load application to the foundation or soil. The load path or lateral-load-resisting system is then analyzed and designed for the corresponding load actions. All components of the system and their connections are verified, and adjustments are made to ensure adequate strength and ductility. In concrete structures, such load paths are achieved by adding new shear walls or by strengthening existing ones. It is not surprising, therefore, to observe that the chosen load path is different from the original system of the structure. Compatibility of the various vertical structural elements of the structure must be investigated to ensure that the selected load path can be activated.

32.4.4 Establish Deformation Compatibility

As discussed earlier, establishing deformation compatibility is essential to ensuring that all structural elements necessary for stability and load transfer have adequate ductility and the ability to redistribute loading to safely withstand the deformations imposed upon them in response to seismic loads. In parking structures where split-level frames are common, post-earthquake investigations and studies have shown that most of the distress was due to column-shear failure in short columns. Measures for the mitigation of column-shear failure vary between existing and new structures. The options introduced in the following sections may be considered for each of the construction types.

32.4.4.1 Retrofit Construction

Retrofitting the column implies one of several options. The first is removing the column and replacing it using an adequate section with close tie spacing. A second option is jacketing the column so its shear capacity can be increased; this can be accomplished by placing vertical and hoop reinforcement around the existing column and by the application of gunite. Another option is to place a two-piece steel jacket and weld it on site. The gap between the existing column and the jacket is then grouted. Epoxy resin and fiber wrapping is another method that is very effective for round or oval columns because the structural contribution of the wrapping is developed through hoop stresses in the wrapping.

32.4.4.2 New Construction

In new construction, short columns can be designed and detailed as a continuous part of the structure to withstand the higher shear forces, or they can be detailed for moment release at their connections to the beam, as shown in Figure 32.12.

FIGURE 32.12 Slip joint at top of short columns.

32.4.5 Establish Adequate Lateral-Load-Resisting System

It is not possible to achieve our goal of ensuring life safety during major seismic events and minimal structural damage during frequently occurring earthquakes just by ensuring that the structure has an adequate vertical lateral-force-resisting system. It is imperative that the seismic force be properly collected at the roof and each floor and properly transferred into the vertical lateral-force-resisting system. Thus, the horizontal concrete diaphragms should be analyzed and strengthened as necessary so this step can be accomplished. The existing vertical resisting system is then strengthened by retrofitting the existing elements or by introducing new elements to supplement the existing capacity. Finally, the existing footing should be investigated and new footings and grade beams should be added where required.

32.4.5.1 Horizontal Diaphragms

In structures constructed prior to 1970, it is very likely that little attention was given to ensuring that the story force could be adequately transferred into the vertical lateral-force-resisting system. As part of the seismic retrofit of the building, methods of ensuring that the diaphragm does not fail should be devised. This can be achieved by introducing chord and drag elements at the floor soffit. Attaching thin steel plates onto the concrete soffit using epoxy resin is a method that can cause little disturbance to the function of the structure yet have very positive results. The connection of the diaphragm to the vertical lateral system should be closely examined. The introduction of steel angles bolted to both the floor soffit and the vertical lateral-force-resisting system is often done with satisfactory results. For diaphragms where a load path into the existing vertical lateral-force-resisting system cannot be reasonably achieved, the layout of the vertical lateral-load-resisting system should be studied. It may be imperative that new vertical members be introduced to allow the establishment of adequate load path.

32.4.5.2 Vertical Load-Resisting System

Existing concrete buildings are most likely to have one of three structural lateral systems:

- Space frame system
- Building frame system
- Bearing wall system

The level of strengthening required to achieve our goal of ensuring public safety and minimal structural damage no doubt differs from one structure to another; however, older buildings with space frames generally require more effort for establishing an adequate vertical lateral-force-resisting system. The following options are some of the available methods for strengthening the vertical lateral-force-resisting systems.

32.4.5.2.1 Introduction of New Concrete/Masonry Shear Walls

This is a method frequently used for retrofitting concrete structures. Shear-wall placement is simpler, in most cases, than adding moment-resisting frames. When the size and location of the new shear walls have been established based on the design force, new footings are placed and connected to the various floor systems by way of drilling and bonding reinforcing steel dowels to the existing slab-on-grade. Wall reinforcements are then placed. Walls can then be formed and poured in place or, as is often the case in recent years, a one-sided form can be placed and gunite applied (refer to Figure 32.13 and Figure 32.14).

32.4.5.2.2 Retrofitting of Existing Walls

In instances where the building layout or architecture offers no option for new shear wall introduction, existing walls may be thickened to the required adequate dimension (Figure 32.15). Additionally, required wall boundary elements at the end of the wall may be added if required, as shown in Figure 32.14. Existing shear walls to be thickened are properly prepared by roughening their surfaces to 0.25-in. amplitude. Appropriate dowels are then drilled and bonded into existing concrete. The required vertical and horizontal reinforcements are tied in place, and concrete is placed either conventionally by installing wall forms and pumping the concrete into place or low-slump gunite is shot in place. It is important to note that the existing footings should be verified for their ability to transfer vertical and horizontal reactions to the ground. It is often necessary to enlarge the existing footings at the thickened shear wall. Additionally, grade beams may be introduced to better defuse the lateral force into the ground.

32.4.5.2.3 Alternative Methods of Seismic Retrofit

So far, the discussion has been limited to the conventional methods for seismic retrofit of buildings where conventional lateral-load-resisting systems are engineered to support the calculated seismic forces that will be developed in a building during severe seismic activity. On the other hand, base isolation is a means by which the seismic response of the structure is significantly reduced by decoupling the building from its seismic forces by: (1) increasing the fundamental vibration period of the structure, or (2) dissipating the energy delivered to the building. Base isolation at the present time is far more expensive

FIGURE 32.13 New concrete wall.

to implement for retrofitting existing structures than conventional methods; however, structures such as historic landmarks and vital buildings that lack an existing load path for seismic forces and have limited capacity in the existing concrete diaphragm or large penetrations in the existing concrete diaphragm that cannot be retrofitted conventionally can be successfully strengthened using base isolation. Some of the primary advantages of the base isolation system include:

- Minimum disruption of important historic features
- Minimum alteration of interior spaces
- Minimum potential damage to architectural finishes during future earthquakes
- Greater degree of life safety to building occupants
- Significantly reduced seismic response
- Significantly reduced story drift

For further information regarding base isolation, the reader is encouraged to consult Naaseh (1995).

FIGURE 32.14 Wall elevation.

32.5 Seismic Analysis and Design of Bridge Structures

32.5.1 Seismic Analysis of Bridge Structures

32.5.1.1 Introduction

In this section, a simple method that models a bridge as a single degree of freedom system is presented. As the bridge model becomes more complicated, however, this simple procedure becomes less accurate; thus, a multimodal dynamic analysis or time-history computer analysis is recommended. There are two basic concepts for bridge seismic analysis. The first is that there is a relationship between the mass and stiffness of a bridge and the forces and displacements that affect the structure during an earthquake; therefore, if we can calculate the mass and the stiffness for our structure, we can obtain the earthquake forces acting on it. The second concept is that bridges are designed to behave nonlinearly for large earthquakes; therefore, the engineer is required to make successive estimates of an equivalent linearized stiffness to obtain the seismic forces and displacements of the bridge.

32.5.1.2 Basics

Mass is a measure of a body's resistance to acceleration. It requires a force of 1 Newton to accelerate 1 kilogram at a rate of 1 meter per second squared. **Stiffness** is a measure of the resistance of a structure to displacement. It is the force (in Newtons) required to move a structure 1 meter. The boundary conditions for the bridge must be carefully studied to determine the stiffness of the structure. **Period** is the time (in seconds) required to complete one cycle of movement. A cycle is the trip from the point of zero displacement to completion of the farthest left and right excursions of the structure and back to the point of zero displacement. **Natural period** is the time a single degree of freedom system will vibrate at in the absence of damping or other forces. Natural period (T) has the following relationship to the mass (m) and stiffness (k) of the system:

$$T = 2\pi\sqrt{\frac{m}{k}} \quad (32.28)$$

Frequency is the inverse of period and can be measured as the number of cycles per second (f) or the number of radians per second (ω) where one cycle equals 2π radians. **Damping** (viscous damping) is a measure of a resistance of a structure to velocity. Bridges are underdamped structures. This means that the displacement of successive cycles becomes smaller. The damping coefficient (c) is the force required to move a structure at a speed of 1 meter per second. **Critical damping** (c_c) is the amount of damping that would cause a structure to stop moving after half a cycle. Bridge engineers describe damping using the damping ratio (ξ) where:

$$\xi = \frac{c}{c_c} \quad (32.29)$$

A damping ratio of 5% is used for most bridge structures.

32.5.1.3 The Force Equation

The force equation for structural dynamics can be derived from Newton's second law:

$$\sum F = ma \quad (32.30)$$

Thus, all the forces acting on a body are equal to its mass times its acceleration. When a structure is acted on by a force, Newton's second law becomes:

$$p - f_s - f_D = mu'' \quad (32.31)$$

FIGURE 32.16 Forces acting on a structure according to Newton's second law.

where:

$$f_s = ku \quad (32.32)$$

is the force due to the stiffness of the structure,

$$f_D = cu' \quad (32.33)$$

is the force due to damping of the structure, and p is the external force acting on the structure (see Figure 32.16). The variables u' and u'' are the first and second derivatives of displacement u , k is the force required for a unit displacement of the structure, and c is a measure of the damping in the system.

Thus, Equation 32.31 can be rearranged as shown in Equation 32.34:

$$mu'' + cu' + ku = p(t) \quad (32.34)$$

However, for earthquakes, the force is not applied at the mass but at the ground (Figure 32.17); therefore, Equation 32.34 becomes:

$$mu'' + c(u' - z') + k(u - z) = p \quad (32.35)$$

for the relative displacement:

$$\omega = u - z \quad (32.36)$$

and the equation of motion, when there is no external force p being applied, is:

$$mu'' + c\omega' + k\omega = -mz'' \quad (32.37)$$

FIGURE 32.17 Earthquake-induced displacements.

FIGURE 32.18 Example response spectra.

In Equation 32.37, mass m , damping factor c , and stiffness k are all known. The support acceleration (z'') can be obtained from accelerogram records of previous earthquakes. Equation 32.37 is a second-order differential equation that can be solved to obtain the relative displacement (u), the relative velocity (\dot{u}), and the relative acceleration (\ddot{u}) for a bridge structure due to an earthquake.

32.5.1.4 Caltrans' Response Spectra

Response spectra have been developed so engineers do not have to solve a differential equation repeatedly to capture the maximum force or displacement of their structure for a given acceleration record. Refer to Figure 32.18 for an example response spectra. Response spectra are graphs of the maximum response (displacement, velocity, or acceleration) of different single degree of freedom systems for a given earthquake record. Thus, engineers can calculate the period of the structure from its mass and stiffness and use the appropriate 5% damped spectra to obtain the response of the structure to the earthquake. The force

FIGURE 32.19 Nonlinear column stiffness.

equation (32.37) showed three responses that can be obtained from a dynamic analysis: displacement, velocity, and acceleration. We can also obtain these using response spectra. The spectral displacement (S_d) and velocity (S_v) can be obtained from the spectral acceleration using the following relationship:

$$Sa = \omega S_v = \omega^2 S_d \quad (32.38)$$

Therefore,

$$S_d = \frac{Sa}{\omega^2} = \frac{Sa}{(2\pi/T)^2} = \frac{T^2 Sa}{4\pi^2} \quad (32.39)$$

Caltrans developed response spectra using five large California earthquake ground motions on rock; 28 different spectra were created based on 4 soil depths and 7 peak ground accelerations (PGAs). Engineers can obtain the earthquake forces on a bridge by picking the appropriate response spectra based on the PGA and soil depth at the bridge site and calculating the natural period of their structure. These response spectra can be found in Caltrans (1995); however, Caltrans is moving toward using site-specific response spectra for many bridge sites.

32.5.1.5 Nonlinear Behavior

Bridge members change stiffness during earthquakes. The stiffness of a column is reduced when the concrete cracks in tension. It is further reduced as the steel begins to yield and plastic hinges form (Figure 32.19). The axial stiffness of a bridge changes in tension and compression as expansion joints open and close. The soil behind the abutment yields for large compressive forces and may not support tension. Engineers must consider all changes of stiffness to accurately obtain force and displacement values for a bridge. Currently, the standard is to calculate cracked stiffness for bridge columns. A value of $I_{cr} = 0.5(I_{gross})$ can be used unless a moment-curvature analysis is warranted. Also, because bridge columns are designed to yield during large earthquakes, the column force obtained from the analysis is reduced by a ductility factor, and the columns are designed for this smaller force. Caltrans is currently using a ductility factor (μ) of about 5 for designing new columns; however, a moment-curvature analysis of columns should be done when the ductility of a column is uncertain.

FIGURE 32.20 Abutment stiffness.

32.5.1.6 Abutment Stiffness

Longitudinally, the soil behind the back wall is assumed to have a stiffness that is related to the area of the back wall as shown in Figure 32.20:

$$k_L = (47,000)(W)(h) \text{ (kN/m)} \quad (32.40)$$

Transversely, the stiffness is considered to be two thirds effective per length of inside wing wall (assuming the wing wall is designed to take the load), and the outside wing wall is only one third effective per wing-wall length for the resultant stiffness shown in Equation 32.41:

$$k_T = (102,000)(b) \text{ (kN/m)} \quad (32.41)$$

An additional stiffness of 7000 kN/m for each pile is added in both directions; therefore, in the longitudinal direction:

$$k_T = (42,000)(W)(h) + (7000)(n) \text{ (kN/m)} \quad (32.42)$$

In the transverse direction:

$$k_T = (102,000)(b) + (7000)(n) \text{ (kN/m)} \quad (32.43)$$

More information on abutment stiffness can be obtained in Caltrans (1995). Bridge abutments are only effective in compression. A gap may have to be closed on seat-type abutments before the soil stiffness is initiated. The abutment stiffness remains linear until it reaches the ultimate strength of 370 kN/m².

32.5.1.7 Parallel and Series Systems

A simplification that allows engineers to analyze by hand many complicated and statically indeterminate structures is the concept of parallel and series structural systems. For a parallel system, all the elements share the same displacement; for a series system, they all share the same force. Also, their stiffnesses are summed differently. By assuming a rigid superstructure or by making other simplifying assumptions, bridge structures can be analyzed as combinations of parallel and series systems. This concept is particularly useful when evaluating the **longitudinal displacement** of the superstructure. Refer to Figure 32.21 and Figure 32.22.

FIGURE 32.21 Parallel structural system.

FIGURE 32.22 Series structural system.

32.5.1.8 Code Requirements

In bridge design, two load cases are considered. Case 1 is for 100% of the transverse force and 30% of the longitudinal force. Case 2 is for 100% of the longitudinal force and 30% of the transverse force. This approach takes care of uncertainty with regard to the earthquake direction and to account for curved and skewed bridges with members that take a vector component of both the longitudinal and transverse force.

32.5.2 Seismic Design of Bridge Structures

32.5.2.1 Introduction

The following collection of guidelines is intended to aid bridge engineers in producing more seismic-resistant bridge designs.

32.5.2.2 Structural System and General Plan

Seismic demands on a structure should be considered conceptually when creating the general plan. First of all, designers can control column demands on superstructures in new bridges by judiciously choosing column sizing, spacing, and flexibility. Second, column or frame stiffnesses must be carefully considered. Column types, shapes, sizes, and length are very important in the design process. Some example concepts that should be considered when establishing the general plan are as follows:

- Column stiffnesses in a frame should preferably be kept within 20% of each other.
- Isolators or sliding bearings can be used at the tops of short, stiff columns adjacent to abutments.
- End diaphragm abutments provide good seismic energy absorbers for short frames (i.e., short length end frame with stiff columns) or short bridges.
- Frames should not exceed 800 ft as a means of avoiding excessive expansion joint movements.
- Reduce joint skew angles to control loss of seat support due to frame rotation.
- Use articulated or single-span bridges in areas of suspected, but poorly defined, faulting.
- Use double columns at expansion joints.

FIGURE 32.23 Example cap joint shear reinforcement skew 0° to 20° .

32.5.2.3 Superstructure Joint Shear

Below is a procedure and example details for determining joint shear reinforcement in box girder bent caps. Typical flexure and shear reinforcement in bent caps shall be supplemented in the vicinity of columns to resist joint shear. Also, the cap width and depth must be sized to limit the joint shear stress to $12 \times (f'_c)^{0.5}$. Minimum cap width shall be 2 ft greater than the column dimension in the cap width direction. The joint shear reinforcement required shall be located within the width of the cap and within a length of the cap equal to (1) two times the column width, or (2) the column width plus two times the bent cap depth, whichever is less. The effective length of cap shall be reduced appropriately for columns located near the end of the cap and closer than the column width or cap depth. Following is a procedure for determining the required reinforcement that must be provided within the specified joint shear zone; the reinforcement is uniformly distributed:

- Vertical reinforcement shall be 20% of the column steel. The quantity of vertical steel shall be a combination of cap stirrups and added bars. Added bars shall be hooked around main longitudinal cap bars. All vertical legs shall be well distributed to provide protection for both longitudinal and transverse demand or be supplemented to produce adequate coverage.
- Horizontal reinforcement shall be stitched across the cap in intermediate layers. The reinforcement shall be hairpin shaped and confine vertical bars in the hairpin bends. The hairpins shall be equivalent in area to 10% of column steel. The hairpins shall be strategically placed in two or more layers, depending on structure depth. Spacing shall be denser outside the column than that used within the column.
- Side-face reinforcement shall be 10% of the main cap reinforcement.
- Provide #4 J-bars at 6 in. on-center along longitudinal top deck bars for bent caps skewed greater than 20° . The bars shall be alternately 24 in. and 30 in. long. Locate the J-bars within a width D either side of the column centerline (D is column dimension).
- All vertical column bars shall be extended as high as practically possible without interfering with main cap bars.
- Column spiral extension into the bent cap shall be replaced by equivalent continuous hoops. This substitution facilitates placement of the various horizontal joint shear bars.

Figure 32.23 shows cap joint shear reinforcement within D distance from the column center line. Figure 32.24 shows cap joint shear reinforcement beyond a distance $D/2$ from the column face.

FIGURE 32.24 Example cap joint shear reinforcement skew 0° to 20° .

32.5.2.4 Superstructure Flexural Capacity

Bridge superstructures must be reinforced to resist longitudinal and transverse flexural demands produced by column plastic hinging. Conventional bar reinforcement must be provided in the slabs and bent caps in the designated zone surrounding the column to satisfy such demands. Prestressing bent caps could be an alternative solution for transverse demands and additionally can supplement joint shear capacity at the column. Pinning column tops in multiple column bents will reduce seismic demand on the superstructure but will require a more expensive fixed foundation.

32.5.2.5 Vertical Accelerations

The 1994 Northridge earthquake gave evidence of acceleration levels for vertical excitations that were higher than those recorded in the past. The flexural and joint shear reinforcement prescribed so caps and superstructures can resist column demands should be ample to provide flexural resistance to vertical acceleration demands; however, the vertical capacity of girder stirrups should be checked, and shear-friction reinforcement in the form of girder side-face reinforcement at the cap that is equal to 1.5 gravity load should be provided. Tie-downs at hinges and abutments might be required.

32.5.2.6 Column Displacement

Displacement demands will generally be determined by STRUDL analysis, although the static method is sufficient for short length bridges (one or two bents). The column displacement capacity can be determined using the push method and is dependent on combinations of vertical and horizontal reinforcement. Also, disconnecting random stiff columns from the superstructure by use of sliding bearings or isolation systems is another means of avoiding large load demands on stiff columns.

32.5.2.7 Flared Columns

Flared columns can create some unexpected demands on the superstructure, footings, and columns. Past policy has assumed that lightly reinforced flares will fuse during severe seismic activity. Superstructures, columns, and footings have been designed to resist plastic hinging demands from the column core at the top and bottom of the column; however, designers must consider alternative behavior. Developing either the full column section at the top of column or hinging at the base of flares should be investigated. Both conditions will significantly affect shear demands in the column and shear and moment demands in superstructures and footings. Flexural reinforcement for caps and superstructures must be calculated if hinging is assumed at the bases of flares.

32.5.2.8 Bent Cap Designs

The design of bent caps for nonseismic loads must be consistent with assumptions made for supports, especially with respect to column flares. If flares are expected to lose structural integrity during seismic loadings, the cap should be designed to carry all loads without benefit of the flares; however, the bridge must be analyzed for all nonseismic load cases with the stiffness and strength of the in-place flares. As in the case with flared columns, the designer must design the cap for double conditions if any type of structural damage or loss of vertical support is anticipated for other types of supports.

32.5.2.9 Footings

New footing design procedures were tested satisfactorily at the University of California, San Diego. Although only one test case was performed, results indicated that serious degradation and bridge collapse can be avoided if standard details are employed. Details included #5 at 12 in. on-center vertical ties and column bar hooks that turned outward. Designers should be cautioned that cantilevered footing sections should not exceed $L/d = 2.5$ (where L is the cantilevered footing length from the column face, and d is the effective depth of footing) in orthogonal directions and $L/d = 30$ diagonally to the footing corner with 70-t piles typically spaced at 3 ft with 1.5-ft edge distances. For higher capacity piles, the designer must ensure load paths through connections, vertical ties, development of flexural reinforcement at footing edges (e.g., hooks), etc. for both tensile and compressive demands.

32.5.2.10 Pile-Design Concepts

The designer should strive to prevent damage in foundations. Piles constructed in competent soil, in combination with passive resistance provided by cap and soil interaction and drag forces, will be sufficient to keep piles in the elastic range for flexure or shear under seismic demand. Problem areas that require guidelines include: (1) piles in soft soils or water, including P-delta effects; (2) pile head conditions, pinned (standard) or fixed (which places tremendous demands on the cap and requires more than nonstandard cap size and reinforcement); (3) pile demands for pile capacities greater than 70 t (e.g., spacing, edge distance, vertical ties that are more dense or of larger size, flexural steel hooks at footing edges); and (4) batter piles (e.g., used in dense soils; not for use in water, soft, or loose soils; capacity in combination with vertical piles). These design concepts are not intended to be a complete list of all conditions or problems or a solution to problems. They are intended to alert designers to conditions where the foundation must have the strength and displacement capacity intended under all conditions of demand.

32.6 Retrofit of Earthquake-Damaged Bridges

32.6.1 Introduction

Since the early 1970s, the California Department of Transportation (Caltrans) has undertaken a major program to ensure the seismic safety of all freeway structures. With a large portion of the work being funded in the aftermath of the Loma Prieta earthquake in 1989, analysis techniques and research to validate such techniques have progressed significantly in the past five years. Early on in the Phase 2 retrofit

program, structure overstrength analysis was the primary tool for seismic vulnerability assessment. Hinges and restrainers were always evaluated but none had been examined after a significant earthquake, so knowledge of their performance was based primarily on laboratory tests and hand calculations. Foundation-strengthening techniques had not been field tested (by real earthquakes), and design methods were based on modified service load tools and simplified assumptions. It was soon clear that these methods, although for the most part very conservative, did not always afford a true picture of the behavior or strength (resistance to collapse) of a structure and did not necessarily produce cost-effective designs. To gain a clearer picture of the performance of bridges, Caltrans engineers have been focusing on the following:

- Load path and limit-state analysis, item input ground motions
- Validity of global models
- Displacement ductility analysis
- Beam and column joint performance
- Hinges and restrainers
- Detailing ductile elements
- Foundation performance

The purpose of this section is to highlight current thinking on these items and help identify available tools to properly retrofit bridge structures.

32.6.2 Background

The goal of retrofitting is to increase the seismic resistance of a bridge to the point of preventing collapse and thereby avoiding loss of life. It is not practical or economical to retrofit all structures to meet the current seismic design performance criteria for new structures. It is, however, our responsibility to ensure that no structure collapses under the maximum credible event. Based on the no-collapse criteria, the primary goal of retrofitting bridges is to ensure that the vertical-load-carrying capacity is maintained. Traditionally, this has meant protecting the ability of the column to carry vertical loads while undergoing cyclic lateral loading. Under this kind of loading, some damage is expected to occur in plastic hinge regions of the column. With 25 years of real-life experience, since the San Fernando Earthquake in 1971, we have been provided with a good picture of where damage can be expected to occur on a concrete structure under seismic loads. These areas include:

- Column plastic hinge regions
- Column shear capacity
- Column-to-footing and column-to-superstructure connections
- Expansion joint openings and hinge restrainers
- Abutment back walls and transverse shear keys
- Pile-to-footing connections
- Pile overload

The following discussions address the seismic analysis and design approaches for retrofitting concrete bridge structures.

32.6.3 Seismic Analysis Approach

32.6.3.1 Load Path and Limit-State Analysis

Limit-state theory says, roughly, that a structure is only as good as the weakest link (or member) in the structural system. Ensuring that plastic action occurs in a predetermined location is therefore the goal. For concrete bridges, this predetermined location is typically, and preferably, in the column. Controlling the location of the plastic hinge allows the engineer to develop a rational estimate of the damage expected to a structure and its ability to resist collapse. For this to happen, all members and components of a

structure must be examined to determine whether they can actually carry the forces required to force plastic hinging to occur in the column. Testing and application of basic engineering principles to components of the structure (column superstructure joints, column–footing connections, pile cap, and pile connections) have shown that areas of analysis and design once taken for granted as adequate could be vulnerable under extreme seismic loading conditions. Rigorous analysis of the structure may determine that the capacity of a system may likely be controlled by connections to the column and not by the strength of the column itself. Current analysis techniques commonly used by engineers to estimate reinforced-concrete capacity strongly suggest that many superstructures do not have the capacity to force plastic hinging into the column. Because one objective of the retrofit is to ensure that plastic hinging does occur in the column, the superstructure strength and ductility have to be addressed in the retrofit design.

32.6.3.2 Global Behavior

Early retrofit analysis typically relied on global elastic modal models to predict moment and displacement demands. Although this is still often a valid analysis technique, in some situations global analyses are not the proper tools for seismic-demand prediction. These situations include but are not limited to:

- Short-period ($T < 0.75$ s) structures
- Very complicated structures (requiring many assumptions)

Other tools that could be used in lieu of or in conjunction with global elastic models include: (1) hand calculations with single degree-of-freedom conditions, and (2) pushover analysis to determine the order of plastic hinging in incremental collapse. Hand-calculation analysis should be limited to simple structures or structures where the number of assumptions is limited. Pushover analysis can be used for both simple and complex structures. The value of pushover analyses is that the capacity of the structural system is accounted for while the integrity of each element is determined. For example, if the two end frames of, say, a three-frame structure are designed with substantially more strength or stiffness than the interior frame, a global analysis may well conclude that the interior frame has relatively low seismic demands when in fact it is being supported, or helped, by the stronger adjacent frames. The final result could still be that the system is adequate to avoid collapse; however, it is important for the engineer to have a clear idea of where vulnerabilities and strengths exist in the system. Because the goal of retrofit is to prevent the collapse and not just prevent plastic hinging, an efficient retrofit analysis technique would explicitly estimate the system capacity at collapse and not just assume a direct correlation between plastic hinging of a single column and precollapse capacity of the system.

32.6.3.3 Displacement and Curvature Ductility Analysis

An alternative estimate of the ductility of a member (column) can be obtained using ductility analysis techniques proposed by Mander et al. (1984, 1988a,b). The implementation of this approach has been tested extensively and directed explicitly toward bridges by Priestly and Seible (1993). The predominant analysis approach until recently has been moment overload—the application of force reduction factors to loads calculated from a dynamic elastic multimodal response spectrum analysis (e.g., STRUDL or SAP90) assuming gross moments of inertia (I_g). This approach tends to underestimate system capacity. The displacement ductility approach focuses on the capacity side of the equation and directly addresses the basic premise of the *equal energy theory*—that displacements are equal for a given load whether the structure remains elastic or enters into the plastic state as long as the section has not blown apart (allowable confinement stresses have been exceeded). By directly calculating the plastic moment capacity (instead of factoring up the nominal moment capacity) and the displacement capacity of each member (instead of limiting displacement to a factor of column geometry without regard to the rotational capacity of the section itself), the engineer can make a more accurate estimate of the capacity of the system. Because the focus in this type of approach is on displacements, it is important to base the analysis on a members effective moments of inertia ($I_{eff} = I_{cr}$) instead of gross moments of inertia. Basing the dynamic

analysis on I_{cr} instead of I_g will result in larger estimated displacement demands and smaller estimated moment (force) demands. More refined analysis techniques can be employed that assess the performance of a member and estimated damage. This kind of information can be of particular interest when attempting to estimate resistance to collapse.

32.6.3.4 Foundations

Footings typically have required extensive work to increase their capacity to a level consistent with the column plastic moment. Early retrofitting techniques were often conservative (for lateral loads) by ignoring the contribution of existing piles to the capacity of the system. Large-scale testing of existing piles had not yet been done *in situ*, so nominal lateral pile capacities were often assumed when existing pile capacity was analyzed. Construction techniques for increasing the capacity of the footing relied on installing standard piles or prestressed tie-downs (tendons or rods). The technology simply had not been developed to make the leap from standard, new bridge construction to efficient, cost-effective retrofit work. Since those early days, many new technologies have come into use in the retrofit industry. Field testing of pile foundations at the Cypress structure in Oakland, and the Terminal Separation in San Francisco have shown that the actual lateral capacity of concrete piles is much greater than was originally thought (90 vs. 40 kips/pile). Note that the assumed tensile capacity of existing piles is most often 0. Pile-to-footing connections were traditionally designed to develop vertical loads in a downward direction (compression), not upward (tension). Construction techniques for installing high-capacity piles (up to 1000 kips/pile) in very confined spaces have been field tested with very promising results. Seismic modeling now takes into account soil springs and group effects instead of simply assuming that all footings are fixed, rigid members. Soil springs in a soft soil may increase the displacement estimate on the column while decreasing the moment demand at the footing. The model may also predict that a footing is moving so much that the piles must be sized to limit displacement or resist larger loads than would otherwise be expected. Liquefaction and large ground displacements along fault rupture zones continue to be items that elude easy solutions.

32.6.4 Design Approaches

32.6.4.1 Retrofit Approaches

The three primary concepts used to retrofit structures are:

- Reduce loads imposed on the system.
- Increase the capacity of the structural elements.
- Provide a new or super element.

It is not uncommon for a retrofit design to make use of more than one of these concepts. The following provides some typical details and ideas that could be used to implement these concepts:

32.6.4.1.1 Column Plastic Hinge Regions and Column Shear Capacity

Steel shells have been used extensively (and successfully throughout California and in Alaska) to add ductility and provide confinement to concrete columns (Figure 32.25). *Composite fiber wrap* provides additional confinement and ductility of concrete columns and is an idea that has been under development for several years; results are starting to yield systems that are economical and structurally equivalent to that of the steel shell (Figure 32.26). *Remove and replace portions of the substructure* is an option that has been used where performance beyond no collapse is required. *SuperBent* provides an additional support system.

32.6.4.1.2 Column-to-Footing Connections and Footings

An additional top mat on footing is a very common retrofit due to the fact that top mats of reinforcement were not used in footings until the late 1970s. The top mat adds tensile capacity to the footing (Figure 32.27). A *prestressed footing* is sometimes used for increased performance.

FIGURE 32.25 Steel casing of column.

FIGURE 32.26 Composite fiber wrap.

FIGURE 32.27 Footing retrofit with additional top mat.

FIGURE 32.28 Bent cap bolsters.

32.6.4.1.3 Column-to-Superstructure Connections

Bent cap bolsters are used to increase the torsional capacity of the bent cap and the capacity of the column and cap joint (Figure 32.28). *Prestressed bent caps* are used to increase the torsional capacity of the bent cap and the capacity of the column and cap joint.

32.6.4.1.4 Expansion Joint Openings and Hinge Restrainers

Place additional or replace existing *restrainers*. *Seat extensions* (typically pipe) allow for displacement. Joint displacement demands are reduced by using additional restrainers.

32.6.4.1.5 Pile-to-Footing Connections

Additional piles can be used to gain greater tension and compression capacity. *Prestressed tie-downs* provide additional footing tensile (only) capacity.

32.6.4.2 Summary

Many more difficulties are encountered in retrofit construction than in standard new bridge construction; however, the field of bridge seismic analysis and retrofit has seen many developments over the past several years. Probably the most significant change in assessing the capacity of a structural system has been the adoption of **ductility analysis** and the pseudo-nonlinear analysis approach of determining a plastic hinging sequence and ultimately a systematic yield mechanism. Construction techniques are quickly adapting to the specialized demands of seismic retrofit for bridges. Materials, techniques, and equipment have been developed and integrated from other industries, such as installation of high-capacity piles (adopted from the oil industry), and new materials such as carbon fiber are being developed in laboratories. The field of seismic retrofitting has developed at a tremendous pace over the last several years. Engineers should expect additional changes as research and construction continue. The techniques used on concrete structures in California have proven to be effective, under real seismic loads (such as the 1994 Northridge earthquake). For additional information on any of the subjects addressed in this chapter, it is strongly suggested that the reader consult the references provided.

32.7 Defining Terms

Base shear—The total design lateral force at the base of a structure.

Bearing wall system—The structural system without a complete vertical-load-carrying frame.

Building frame system—An essentially complete frame that provides support for dead, live, and snow loads.

Boundary element—Special reinforcement at edges of openings, shear walls, or diaphragms.

Diaphragm—A horizontal system acting to transmit seismic forces to vertical lateral-force-resisting systems.

Dual system—A combination of shear walls or braced frames and intermediate or special moment-resisting frames proportionally designed to resist seismic forces.

Hoop—A closed tie that may be of several reinforcing elements with 135° hooks having a 6-bar diameter (3-in. minimum) extension at each end or a continuously wound tie with a 135° hook at each end with a 6-bar diameter extension (3-in. minimum) that engages the longitudinal reinforcement.

Moment-resisting frame—A frame where the frame members and joints are capable of resisting forces primarily by flexure.

Shear wall—A wall designed to resist seismic forces parallel to the plane of the wall.

Story drift—The displacement of one level relative to the level above or below.

Strength—The useable capacity of a structure or its structural members to resist lateral loads within the code-allowable deformations.

Structure base—That level in the structure at which the earthquake motions are considered to be imparted to the structure.

33.1 Practical Applications

A prefabricated concrete bridge element is defined as part of a bridge that is precast away from its final position (Sprinkel, 1985). A system is a combination of elements. Prefabricated concrete bridge elements and systems are used to construct new bridges and to rehabilitate or replace old ones. Prefabricated elements can reduce design effort, enhance quality, simplify and expedite construction, lessen inconvenience to the traveling public, improve safety for workers and the traveling public, and minimize cost. Design effort can be reduced when the same design is used on multiple bridge projects. Historically, bridge-design engineers have customized bridge designs for each site, making the prefabrication of elements impractical except for use on major multiple-span bridge projects. Recent efforts have involved making more adjustments to the site to accommodate a standard design and have developed designs that are more versatile. Fabricating elements in the controlled environment of a precast or prestressed concrete plant enhances quality. Plants are typically certified and well established, although temporary on-site plants are constructed to produce elements for a major bridge project. Plants can use high-quality reusable forms; temperature, relative humidity, and wind can be controlled; the concrete can be batched at the plant; and labor is more efficient because tasks are repeated.

Prefabricated elements, set in place at the bridge site, simplify and expedite construction by minimizing forming, form removal, and placing and curing concrete in a difficult-to-control environment. In addition, prefabricating the bridge element away from its final location minimizes traffic safety issues for both the

* Associate Director, Virginia Transportation Research Council, Charlottesville, Virginia, and Section Head, Transportation Research Board; expert in materials and construction, particularly public works.

traveling public and the worker and minimizes delays and inconvenience for the motorist. Lanes can be open during peak travel periods and closed during off-peak periods for the rapid replacement of bridge sections. Once in place, the fully cured element is ready to receive traffic. Polymer concrete and high-early-strength patching materials now make the rapid connection of prefabricated elements easier. The most significant reasons to use prefabricated elements include the economy realized from the repeated use of forms, the reduction in on-site construction time, and improved safety because of the rapid construction. Initial construction costs can be lower, depending on the costs for cast-in-place concrete construction. Life-cycle costs will likely be lower because of the higher quality and longer life of the structure. When the costs of delays and inconvenience to the motorist are considered, prefabricated elements that can be assembled and put into use during off-peak traffic periods will almost always be economical. Prefabricated elements are increasingly popular as highway funds are used to rehabilitate and replace deteriorating bridges. Bridges with high volumes of traffic can usually only be replaced during off-peak traffic periods (at night or on weekends), and prefabricated elements provide an attractive solution. Mass-produced, easily assembled elements are just as practical for replacing bridges on low-volume roads.

Prefabricated elements, however, are not the best solution for every bridge construction and replacement project. The demand for a particular shape may be too low to justify an investment in forms. Shipping costs may be too high because the nearest plant is hundreds of miles away. Connection details may cause maintenance problems that result in a higher life-cycle cost. An advantage of concrete is that it can be formed into almost any shape; thus, the architectural and site requirements for a bridge may be so complicated that custom on-site forming is required and the prefabrication of elements is not practical. A decision-making tool can be used to decide whether or not a prefabricated bridge is effective for a specific location (Rawls, 2006).

A 1984 survey indicated that the use of prefabricated bridge elements was increasing and that the structures were economical in many situations (Hill and Shirole, 1984). Earlier applications included precast and prestressed slabs and I-beams for simple spans. Later, use expanded to include subdeck panels, deck slabs, parapets, and substructure elements. Currently, all elements in a bridge can be economically constructed or replaced with prefabricated ones. Entire spans and bridges can be moved into place with a brief road closure.

In the past, cranes were typically used to move large bridge elements into place. Recent developments with bridge-moving systems have facilitated the rapid replacement of entire bridges or bridge spans (FHWA, 2004). The new systems include self-propelled modular trailers that are multi-axle, computer-controlled vehicles that can move in any horizontal direction without damaging or deforming the element. Other systems include special load frames, modular jacking systems, horizontally skidding or sliding systems, incremental launching systems, floating barges, and vertically lifting systems.

High-performance concrete mixtures containing pozzolans and admixtures have led to the fabrication of elements with concrete compressive strengths in excess of 10,000 psi (68.9 MPa). The higher quality concretes allow smaller cross-sections, longer spans, greater girder spacings, and longer service. A variety of deck wearing and protection systems can be placed on the prefabricated elements to provide a smooth-riding, skid-resistant surface that retards the penetration of chlorides and water. Wearing and protection systems that have been used include a thin bonded hydraulic cement concrete overlay, waterproof membrane overlaid with asphalt, thin bonded epoxy concrete overlay, additional monolithically cast concrete on the precast element, and low-permeability concrete in the precast element (Sprinkel, 2004).

Already in the new millennium, many publications have supported the use of prefabricated bridge elements and systems. In response to public demand for minimized traffic disruption, the Texas Department of Transportation has been a leader in the use of prefabricated bridge elements in bridge design and construction (Pruski et al., 2002). Prefabricated bridges are meeting growing market demands for fast and efficient structures (Johnson, 2002). New girder designs, strand technologies, and concrete mixes are making precast prestressed concrete bridges more popular (Dick, 2002). New guidelines and load and resistance factor design (LRFD) specifications for full-depth, precast-concrete bridge deck panel systems with no overlays or post-tensioning are now available (Badie et al., 2006). According to the Federal Highway Administration (FHWA), the use of prefabricated elements can improve construction

FIGURE 33.1 Slab span. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

zone safety, minimize the traffic impacts, and improve constructability (FHWA, 2002). A brochure provides descriptions of 15 bridge projects that solved site-specific challenges using prefabricated bridge elements and systems (AASHTO, 2002). Implementation efforts by the Federal Highway Administration and the American Association of State Highway and Transportation Officials (AASHTO) have significantly increased the acceptance and use of prefabricated bridge elements and systems (AASHTO, 2004; FHWA, 2003; FHWA/AASHTO, 2004).

33.2 Types of Elements

The most frequently used prefabricated concrete elements and systems are the prestressed I-beam, prestressed box beam, prestressed channel, and slab span (Sprinkel, 1985). The prestressed subdeck panel was frequently used in the late 1970s and 1980s, but such use has declined in recent years because of reflective cracking in the site-cast overlay concrete. Precast parapets have been used on occasion, but problems with leakage under the parapet have curtailed acceptance. Recent years have seen increased interest in post-tensioned segmental construction for economy in medium and long spans, substructure elements to reduce the environmental impact of construction, and full-depth deck replacement slabs to facilitate the rapid replacement of decks during off-peak traffic periods. Longitudinal, partial-depth, or full-depth deck slabs that are precast on one or more concrete or steel beams have also been successfully used (FHWA, 2004).

33.2.1 Precast and Prestressed Slab Spans

Slab span elements (Figure 33.1) may be cast in various widths, depths, and lengths to accommodate spans up to 50 ft (15 m) (Table 33.1). Shorter slabs may be conventionally reinforced and fabricated at simple precast plants. Longer slabs are typically voided and prestressed or post-tensioned (PCI, 1975; VTRC, 1980). Slabs are easy to fabricate, transport, and erect. Department of Transportation (DOT) bridge crews have precast slabs (Sprinkel, 1976).

TABLE 33.1 Typical Span Lengths for Elements

Element	Length (ft)	Length (m)
Precast slab span	10–30	3–9
Prestressed slab span	20–50	6–15
Multi-stemmed beam	25–50	8–15
Prestressed double-tee and channel	20–60	6–18
Prestressed inverted channel	30–80	9–24
Prestressed single-tee	30–80	9–24
Prestressed I-beam	40–100	12–30
Prestressed box beam	50–100	15–30
Prestressed bulb-tee	60–80	18–24
Post-tensioned segmental	50–400	15–122

33.2.2 Multi-Stemmed Beam

Multi-stemmed beams (Figure 33.2) may be cast in various lengths and increments of width to accommodate short spans. Weld plates and grouted keyways provide shear transfer between beams.

33.2.3 Prestressed Double-Tee and Channel

Most prestressed concrete producers have forms for fabricating double-tees and channels for use in building construction. Additional prestressing, wider webs, and thicker flanges are typically required for bridge loadings (Figure 33.3) (Tokerud, 1975). Forms have been modified and new forms fabricated to produce members for highway applications when there has been sufficient support provided by a DOT to justify the investment in forms (Sprinkel and Alcock, 1977). Channel beams and double-tees are typically used for medium-length spans, and shear transfer between beams is typically provided by grouted keyways or weld plates. Site-cast concrete is usually placed as an overlay, but channel and double-tee members have been overlaid with asphalt (PCI, 1975).

FIGURE 33.2 Multi-stemmed beam. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

FIGURE 33.3 Double-tee and channel. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

FIGURE 33.4 Prestressed inverted channel. (From Sprinkel, M.M. 1985. *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C.)

33.2.4 Prestressed Inverted Channel

The inverted channel (Figure 33.4) may be cast in the inverted position or cast in conventional channel forms and inverted before erection at the bridge site. Longer spans can be achieved in the inverted position because more prestressing can be placed in the bottom of the beam. The Missouri Department of Transportation used the inverted channel on many bridges (Salmons, 1971). Site-cast concrete must be

FIGURE 33.5 Prestressed single-tee. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

placed to connect the channels and provide a deck surface. An alternative to the channel is inverted T-beams placed adjacent to each other and then made composite with cast-in-place concrete placed between the webs of the tees and over the tops of the stems to form a solid member (see FHWA, 2004).

33.2.5 Prestressed Single-Tee

Prestressed single-tee beams are used in building construction. Prestressed concrete plants can sometimes fabricate the beams for shorter spans using the same forms as used in building construction with additional prestressing strands to accommodate the heavier loading. With adequate support from a DOT, a precast producer can invest in new forms to produce longer span beams (Figure 33.5) suitable for highway loadings (Sprinkel and Alcock, 1977). The single-tee is unstable by design and must be supported at the bridge site to prevent overturning until the diaphragms can be cast and the keyways grouted. Site-cast concrete is usually placed to connect the tees and to provide a deck (Sprinkel, 1978). An asphalt wearing surface can be used when the flange of the tee is thick enough to accommodate shear loads.

33.2.6 Prestressed I-Beams

The prestressed I-beam (Figure 33.6) is the prefabricated element most used by DOTs (Sprinkel, 1985). Many prestressed concrete producers invested in forms during the construction of the interstate system. The standard AASHTO cross-sections simplify design and provide for mass production (Panak, 1982). The beams, cast in a variety of widths and depths, are economical for spans of 40 to 100 ft (12 to 30 m). Spans up to 140 ft (43 m) have been constructed (Anderson, 1972; PCI, 1975). Longer spans can be achieved by field-connecting the beams end to end and post-tensioning them (Fadl et al., 1977; Oesterle et al., 1989). The prestressed beams can be positioned more rapidly than a site-cast concrete beam can be constructed. For convenience, other elements are typically constructed with site-cast concrete, limiting the economy of mass production and rapid assembly to the beams. Prestressed concrete subdeck panels have been used, and a National Cooperative Highway Research Program (NCHRP) publication, *Rapid Replacement of Bridge Decks*, addresses the development of designs for prestressed full-depth deck panels

FIGURE 33.6 Prestressed I-beam. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

FIGURE 33.7 Prestressed box beam. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

to be used with the beams (Tadros and Baishya, 1998). A recently completed NCHRP project, *Full-Depth, Precast-Concrete Bridge Deck Panel Systems*, includes designs for full-depth, precast deck panels without post-tensioning and overlays (Badie et al., 2006).

33.2.7 Prestressed Box Beams

The box beam (Figure 33.7) may be precast in a range of widths, depths, and lengths to accommodate spans of approximately 50 to 100 ft (15 to 30 m) (PCI, 1975). Boxes placed next to each other are typically tensioned in the transverse direction and covered with a wearing surface of asphalt. Boxes spaced apart

FIGURE 33.9 Post-tensioned segmental construction. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

33.2.9 Segmental Construction

Elements (Figure 33.9) are typically full width, match cast, prestressed in the transverse direction, and post-tensioned in the longitudinal direction (VTRC, 1981). The elements are suitable for use on a wide range of span lengths. For shorter spans, the elements are usually erected on false work or assembled on a truss supported from pier to pier. For longer spans, the elements are erected by balanced cantilever, incremental launching, or progressive placing (Sprinkel, 1985). A patented segmental concrete overpass system economical for spans of 50 to 115 ft (15 to 35 m) provides at least 2 to 3 ft (0.6 to 0.9 m) of increased under-clearance and halves the on-site construction time for a two-span structure (Freyermuth, 1996). A procedure for the economical replacement of the top slab of a precast post-tensioned segmental bridge has recently been developed, so deck deterioration will not require the replacement of the superstructure (Stelmack and Trapani, 1991).

33.2.10 Prestressed Subdeck Panels

Prestressed subdeck panels are cast in a variety of lengths and widths, typically 4 to 8 ft (1.2 to 2.4 m). The length is a function of the spacing of the supporting beams. The panels are typically 3.5 in. (89 mm) thick and are set in a bed of grout about 0.5 in. (13 mm) thick. Site-cast concrete is placed over the panels to provide a reinforced deck (Figure 33.10). The panels are easily installed with a small crane and several laborers and do not require temporary forms or platforms to work from. Cracks usually occur in the site-cast concrete directly above the joints between the panels; consequently, many DOTs have discontinued or restricted the use of the panels. Cracking is less pronounced when the panels are placed on prestressed girders with short spans. Precast concrete subdeck panels can provide an economical and rapidly constructed deck (PCI, 1987).

33.2.11 Precast and Prestressed Deck Slabs

The deck is usually the first element in a bridge to deteriorate and to require funds for rehabilitation. In situations where traffic volumes are high, it is often necessary to rehabilitate or replace the deck in sections during off-peak periods. Because of the time required for site-cast concrete to cure, a number

FIGURE 33.10 Prestressed subdeck panels. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

of replacement strategies have been developed using prefabricated deck slabs (Issa et al., 1995a,b). Most of the systems involve a transverse segment (Figure 33.11) connected to the supporting beams with a rapid-curing polymer or hydraulic cement concrete. Shear transfer between adjacent slabs is achieved through the use of grouted keyways, site-cast concrete, and post-tensioning. Composite action is achieved through the use of studs on steel beams that extend into voided areas in the slabs that are then filled with polymer or hydraulic cement concrete.

Precast slabs can behave in a full-composite manner when connected to steel stringers with studs and epoxy mortar and when keyways are grouted with epoxy mortar (Osegueda et al., 1989). An earlier study identified some suitable connection details and concluded that the deck slabs are more economical than site-cast concrete because of the structural efficiency provided by post-tensioning and prestressing and because of the reduced construction time (Berger, 1983). Improved connection details for the use of panels on steel beams and prestressed concrete beams have been developed (Tadros and Baishya, 1998). More recently, a special loop bar reinforcement detail has been developed to provide live load distribution across transverse and longitudinal joints (see FHWA, 2004). A new full-depth precast prestressed concrete bridge deck slab system has been developed that includes stemmed slabs, transverse grouted joints, longitudinal post-tensioning, and welded threaded and headless studs (Tadros and Baishya, 1998). The deck slabs are thinner and lighter than a conventional deck and can be constructed faster.

Prestressed deck slabs typically have been used on major bridge deck replacement projects (Figure 33.12) such as the Woodrow Wilson Bridge (Lutz and Scalia, 1984). Also, most replacements have involved the use of transverse slabs. The decks on the George Washington Memorial Parkway were replaced using precast longitudinally post-tensioned transverse deck slabs (Jakovich and Alvarez, 2002). A latex-modified

FIGURE 33.11 Prestressed deck slabs. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

FIGURE 33.12 Prestressed post-tensioned deck slabs were installed at night to replace the deck of the Woodrow Wilson Bridge.

FIGURE 33.13 Special loop bar connection detail for deck slabs. (From FHA, *Prefabricated Bridge Elements and Systems in Japan and Europe*, Summary Report, International Technology Exchange Programs, Federal Highway Administration, Washington, D.C., 2004; <http://www.fhwa.dot.gov/bridge/prefab/pbesscan.htm>.)

concrete overlay was placed over the slabs. The truss spans of the deck on I-95 in Richmond, Virginia, were recently replaced with night lane closures using the full-depth transverse deck slabs (Figure 33.13). The slabs were also used to replace the deck on Route 50 in Fairfax County, Virginia (Babaei et al., 2001). The Virginia Department of Transportation first used transverse precast deck slabs to replace a deck on Route 235 over Dogue Creek in Fairfax County in 1981 (Sprinkel, 1982). Longitudinal slabs were successfully used to rehabilitate the Freemont Street Bridge (Smyers, 1984), and a new bridge was built in Thailand (Zeyher, 2003).

Longitudinal, partial-depth, or full-depth deck slabs that are precast on one or more concrete or steel beams have also been used successfully (FHWA, 2004). The superstructure elements are set next to each other and are typically connected by transverse post-tensioning in the deck and diaphragms between the beams. Keyways in the deck are grouted. The deck on I-95 in Richmond, Virginia, was recently replaced with night lane closures using the full-depth deck slabs on steel beam superstructure elements. When partial depth deck superstructure elements are set next to each other, reinforced site-cast concrete facilitates the connection of the elements.

33.2.12 Precast Parapet

The precast parapet (Figure 33.14) lends itself to prefabrication because it has a standard shape and can be easily mass produced. Several connection details have been developed to anchor the parapet. The parapet has been used in a number of states, but acceptance has been slow because of problems with water and chloride solutions leaking between the base of the parapet and the top of the deck.

33.2.13 Substructure Elements

More time is usually required to construct the substructure than the superstructure, and major reductions in construction time can be achieved by prefabricating the elements of the substructure. Most substructure elements have been prefabricated. Examples include pilings, piers, pier caps, abutments, and wing walls. Figure 33.15 shows abutment and wing-wall panels placed on temporary pads and anchored with weld plates and a site-cast concrete footing (PCI, 1975). To simplify erection, abutment and wing-wall elements have been precast with the footing and set on a site-cast footing (Sprinkel, 1985). Prestressed piling has been used for years, but pile caps are usually site cast. Bridges with prefabricated piers, pier caps, abutments, and wing walls are limited in number but use is increasing, particularly by the Texas Department of Transportation (Billington et al., 1999; Matsumoto et al., 2001, 2002). A bridge with a

FIGURE 33.14 Precast parapet. (From Sprinkel, M.M., *Prefabricated Bridge Elements and Systems*, NCHRP Synthesis 119, Transportation Research Board, Washington, D.C., 1985.)

FIGURE 33.16 Prefabricated pier segments.

FIGURE 33.17 Precast concrete pier bent. (Figure courtesy of the Texas Department of Transportation, Dallas.)

precast abutment was recently constructed in Pennsylvania (Scanlon et al., 2002). It is difficult to standardize the elements because of differences between bridge sites and between piers at the same site that involve soil characteristics, location of bedrock, and the depth at which acceptable bearing can be obtained (Ganga Rao, 1978). A well-known example of the use of prefabricated piers is the Linn Cove Viaduct (Anon., 1984). The entire bridge was prefabricated to minimize environmental impact. Precast segmental superstructure segments were progressively placed and post-tensioned until a pier location was reached. Working from the cantilevered superstructure, holes were drilled into the ground. Prestressed piles were placed in the holes, and precast pier segments were placed and post-tensioned together. Site-cast concrete was placed around the bottom segment (Figure 33.16). The SPER system is a method of rapid construction of piers using precast concrete panels as both structural elements and formwork for cast-in-place concrete (see FHWA, 2004). The Texas Department of Transportation has developed and used a precast pier bent (Figure 33.17). The bent is placed on piers, and the voids in the bent around the reinforcement that extends from the piers are filled with grout.

FIGURE 33.18 Precast culverts.

33.2.14 Precast Culverts

Culverts can be used instead of bridges in situations where the cross-section will not restrict flow. Culverts are easy to install, do not have a deck to deteriorate, and seldom require extensive plans. Culverts cannot be used on navigable streams. Precast culvert designs (Figure 33.18) include the pipe, box, inverted U, and arch. Site-cast footings and end walls are typically used with the inverted U and the arch. Concrete pipe is used for spans of 1 to 10 ft (0.3 to 3 m), and concrete boxes are used for spans of 4 to 12 ft (1.2 to 3.7 m) (Concrete Pipe and Products Company, 1993). Precast U-shaped culverts have been used for spans up to 16 ft (4.9 m), and the arch shape has been used for 40-ft (12-m) spans (Conspan Bridge Systems, Inc., 1995; Lambert, 1982).

33.3 Construction Considerations

On-site construction time is typically reduced when prefabricated elements are used because the concrete forming, casting, and curing occur at a precast plant. Quality elements are typically produced under controlled conditions. Elements are typically inspected at the plant and approved for shipment. Elements should fit together at the site when they are fabricated to the tolerances prescribed by the Prestressed Concrete Institute (PCI, 1977, 1978). Precasting operations should be organized to minimize the number of times an element must be moved. Excessive handling is costly and time consuming and increases the chances for damage (Waddell, 1974). The contractor should have an approved erection plan. Proper communication between the fabricator and contractor is essential. Elements should be delivered in the order in which they are to be assembled. Each element should be checked for damage that might have occurred during delivery and the plant stamp of approval should be verified. The hardware, rigging, and equipment required for handling the elements and the lifting locations should be preapproved before lifting an element. Handling and erection stresses can be greater than in-service stresses. Care should be taken to keep the stresses to a minimum. When feasible, elements should be supported during erection

as they are during delivery and storage. When lifting equipment is to be placed on the structure, the design should be checked and approved to ensure that the structure is not overstressed. Lifting equipment should be large enough to handle the elements. It is better to have equipment that is too large than too small.

Before placing elements, bearing areas should be properly prepared. Elements that fit properly can be assembled in a few minutes. Additional time is required to make corrections for improperly fitting elements. The advantage of match casting elements is a good fit. Several mortars and grouts for hydraulic cement and polymer concrete have been developed to facilitate the erection and connection of prefabricated elements (Gulyas et al., 1995). Temporary shims may be used. High-early-strength mortars and grouts can anchor the elements in a short time. When the elements have been assembled, a wearing and protection surface is usually installed. Asphalt is popular because of its low cost, but it should be used in connection with a properly installed membrane to prevent the infiltration of water and chloride ions into the prefabricated elements. Hydraulic cement concrete overlays can be installed to provide the final wearing surface. Bonded hydraulic cement concrete overlays can have a life of 30 years or more; however, these overlays are not easy to install, and construction should be done according to recommended practice. The recent failures of a number of bonded concrete overlays on major bridges before opening them to traffic or shortly thereafter illustrate the difficulties associated with constructing a successful overlay. Thin epoxy overlays have been used successfully as a wearing and protection system. Finally, deck elements can be precast with the final wearing surface, and irregularities can be removed by shot blasting or grinding the surface to provide good ride quality (Sprinkel, 2004).

33.4 Looking Ahead

The use of prefabricated bridge elements and systems will continue to increase for many reasons. With prefabrication, the work force can be more productive and can produce a better product in the controlled environment of a precast plant, compared to forming and placing reinforcement and concrete outdoors. The enhanced productivity and quality promote economy. The need to replace bridges and bridge elements is growing as our transportation system ages. The number of structures subjected to high volumes of traffic also continues to increase. Element replacement during off-peak traffic periods is becoming a necessity, and replacement with prefabricated elements is one of the few feasible options. Reducing delays for the traveling public is an additional economic incentive to use prefabricated elements. In recent years, the connection details that have caused maintenance problems and reduced the service life of elements have been improved. Better designs, enhanced materials, and more post-tensioning are allowing the construction of bridges with prefabricated elements that are more economical on a life-cycle basis than bridges constructed with site-cast concrete. There will always be a place for site-cast concrete, because concrete can take the shape of any form in which it is placed. This flexibility and versatility are necessary to satisfy many construction needs. It would be foolish to try to prefabricate concrete for every situation. Even so, the outlook for prefabricated bridge elements and systems has never been better. The use of prefabricated bridge elements and systems has increased significantly since the first edition of this *Handbook* was published. Universities, state DOTs, the FHWA, and the bridge industry have taken leadership roles in the new developments. The FHWA Summary of Prefabricated Bridge Elements and Systems website provides abstracts and contact information for recent publications on the subject (FHWA, 2004). Use will continue to increase as our roadways become more congested.

34.1 Introduction

The precasting of concrete offers a wide variety of fabrication and assembly options. Economical seismic solutions are, to a large extent, dependent on the fabricator's capabilities and the contractor's comfort with the manner in which a particular precast component or system is integrated into the building. As a consequence, innovation is the key to creating a successful solution because the options are many. From a design perspective, options can be placed in two categories: those that emulate cast-in-place concrete construction and those that provide connections between components that are capable of sustaining post-yield deformations. We will refer to these design alternatives as *emulative* and *yielding*, respectively. The term *jointed precast* is also used to identify precast concrete elements designed to yield at the precast interface (Ghosh and Hawkins, 2001). These two approaches are shown in Figure 34.1. Systems a, b, and d of Figure 34.1 are emulative, for post-yield rotations are expected to occur in the concrete beam away from the point at which precast members are connected. Yielding systems similar to that described in Figure 34.1c are the exclusive focus of this chapter.

* Chairman Emeritus of Englekirk Companies and Adjunct Professor of Structural Engineering at the University of California, San Diego, where he actively participates in structural engineering research and teaches graduate courses in reinforced and prestressed concrete design.

34.2 Basic Concepts

The cost-effective development of a yielding connector requires a simple yet effective mechanism for transferring both shear and moment as well as a suitable means of developing a strength-based loading criterion. Accordingly, these basic design and load transfer mechanisms are discussed before we explore the design of component and building systems.

34.2.1 The Development of a Strength Criterion

The introduction of a yield limit state at the point where the demand is expected to be a maximum (Figure 34.1) suggests that limit-state design procedures should be used to develop objective levels of system strength. Further, adjusting the level of provided strength is much more difficult in precast assemblies where the transfer mechanisms have established capacities that are large and do not allow modest changes in provided strength. Accordingly, a mechanism approach should be used to define the strength limit state for a precast concrete system. The mechanism approach should have as its primary objective entirely discounting the impact of dead and live loads on seismic bracing programs. The mechanism approach was introduced as *plastic design* in the 1950s and then was exclusively applied to indeterminate steel systems. The mechanism approach recognizes that system strength is based on the load required to produce a mechanism in the system and that first yield, as a limit state, does not produce consistent factors of safety.

FIGURE 34.3 Subassembly mechanisms. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

Consider the frame and extracted subassembly described in Figure 34.2. The strength limit state is defined by one of the mechanisms shown in Figure 34.3. Observe that dead and live loads only impact mechanisms of Figure 34.3a and Figure 34.3b because, in the mechanism of Figure 34.3c, dead and live loads create no external work. Our seismic design objective should be to ensure that the mechanism described in Figure 34.3c precedes that described in Figure 34.3b. This objective is accomplished by comparing the lateral loads required to create the two mechanisms described in Figures 34.3b and 34.3c:

Mechanism of Figure 34.3c

$$\begin{aligned} \text{External Work} &= \text{Internal Work} \\ V_{uE} h_x \theta &= 2M_p \theta \end{aligned} \quad (34.1)$$

where M_p is assumed to be the nominal strength of the connecting assembly.

Mechanism of Figure 34.3b

$$\begin{aligned} \text{External Work} &= \text{Internal Work} \\ V_{uE} h_x \theta + 2(w_{uD} + w_{uL}) \left(\frac{\ell}{2} \right) \left(\frac{\ell}{4} \right) \theta &= 2M_p \theta + 2M_{p1} \theta \end{aligned} \quad (34.2)$$

where M_{p1} is the internal strength of the beam, assumed to be critical at midspan.

FIGURE 34.4 Internal mechanism. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

The design objective is to determine the strength relationship between the internally provided flexural strength (M_{p1}) and that provided at the ends of the beam (M_p) that would cause the mechanism of Figure 34.3c to be critical. If we define A as:

$$A = \frac{M_{p1}}{M_p} \quad (34.3)$$

then M_{p1} , the strength provided in the interior of the beam, must be greater than AM_p to attain our objective—the dominance of the side-sway mechanism (Figure 34.3c). Accordingly,

$$(A = 1)M_p > (w_{uD} + w_{uL})\frac{\ell^2}{8} + \frac{V_{uE}h_x}{2} \quad (34.4)$$

Thus, if the strength of the internal plastic hinge (AM_p) exceeds $(w_{uD} + w_{uL})\ell^2/8$ and the provided moment capacity at the support is equivalent to or larger than M_p as developed by the mechanism of Figure 34.3c ($([V_{uE}h_x]/2)$), the impact of vertical loads on the design strength provided in the yielding connector may be neglected.

Example

The 24-foot internal bay of the frame of Figure 34.2 is shown in Figure 34.4:

$$\begin{aligned} \text{External Work} &= \text{Internal Work} \\ 2\frac{V_E}{2}h_x\theta + 2w_u\left(\frac{\ell}{2}\right)\frac{\ell}{4}\theta &= 2M_p\theta + 2M_{p1}\theta \end{aligned} \quad (34.5)$$

Use Equation 34.5 to solve for the minimum value of M_{p1} if M_p is 825 ft-kips:

$$\begin{aligned} 200(9) + \frac{2.22(24)^2}{4} &= 2(825) + 2M_{p1}, \quad M_{p1} > 235 \text{ ft-kips} \\ A = \frac{M_{p1}}{M_p} &= \frac{235}{825} = 0.28 \end{aligned}$$

Observe that the design objective can be obtained by the direct application of Equation 34.2 because it is understood that Equation 34.1 must be satisfied.

Conclusion: The side-sway mechanism described in Figure 34.3b can be avoided if the strength of the beam (M_{p1}) is enough to satisfy the demand suggested by unconstrained support rotations.

FIGURE 34.7 Shear transfer mechanisms at the beam–column interface. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

34.2.3 Creating an Effective Shear Transfer

Shear transfer in cast-in-place concrete regions of discontinuity, such as the beam–column interface described in Figure 34.7, relies on the toe region of the beam to transfer both compression and shear. This shear transfer mechanism is often referred to as *shear friction*. Essentially, the yielding of the flexural tension reinforcing of the beam is assumed to create a frictional resistance by its equilibrating compressive counterpart. The basic shear transfer strength as developed in design standards implies a shear friction factor (μ) of 0.6 to 1.4. This large range of codified friction factors is attributed to the condition of the interface where shear must be transferred. Figure 34.8 describes the interface when applied shear acts in one direction. Seismic cyclings cause the actions to reverse, and tension cracks in the top of the beam described in Figure 34.8 will close and be subjected to shear. The deterioration described in Figure 34.5, exacerbated by the buckling of the bars, will occur and create a deformation limit state. Accordingly, the shear transfer limit state is not, given a cyclic deformation, a function of the initial interface surface but rather the propensity of the interface to deteriorate. Yielding precast systems will rely on friction to transfer shear and endeavor to minimize cyclic deterioration. Yielding precast joints will often rely on a steel-to-steel or a steel-to-concrete interface, for they are also capable of transferring shear forces when the frictional demand is reasonable. The steel-to-concrete friction factor is on the order of 0.7; structural steel design procedures allow a steel-to-steel friction factor of 0.35 for clean mill-surfaced finishes based on a factor safety of between 1.4 and 1.5.

FIGURE 34.8 Compression fan at interior support of the beam, monotonic loading. (From McGregor, J., *Reinforced Concrete: Mechanics and Design*, 3rd ed., Pearson Education, Upper Saddle River, NJ, 1997. With permission.)

FIGURE 34.9 Isometric view of the Dywidag Ductile Connector (DDC[®]) system. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

Conclusion: The use of a nominal friction coefficient of 0.5 for steel-to-steel and 1.0 for concrete-to-concrete regardless of the type of surface finish seems reasonable. A strength reduction factor of 0.85 is often recommended but probably excessive in this case, for the compressive force is passively activated and always proportional to shear demand. This constant relationship between moment and shear obviates the need to consider overstrength factors.

34.3 Precast Concrete Seismic Moment-Resisting Ductile Frame Systems

Two basic systems are developed in this section. They have both been used successfully to construct major buildings in regions of high seismicity and represent two approaches to creating precast concrete buildings that will perform well when subjected to seismic excitations. The described approaches differ primarily in the means by which the frame beam and column are connected. They are categorized herein as *bolted* and *post-tensioned*, but it is important to realize that the concepts developed are not limiting in their potential application, for variants have been and will continue to be produced.

34.3.1 Bolted Assemblages

The development of the assemblage described in Figure 34.9 was motivated by a desire to improve post-yield behavior of concrete ductile frames, because the ultimate post-yield rotation capability of the subassembly is increased by 50%. The adaptation of the ductile connection concept to precast concrete is logical, because it allows post-yield deformations to be accommodated where members are joined (Figure 34.1c). Direct-thread alternatives have been used in both cast-in-place systems and composite precast concrete systems. The desired behavior is accomplished through a merging of steel technology with the basic objectives of seismic-load-limiting principles essential to the development of ductile behavior in structural systems that must survive earthquakes. The basic component is the *ductile rod* (Figure 34.10), which is capable of attaining strain states in excess of 30%. The assemblage described in Figure 34.9 allows tolerance in all directions and ensures proper seating of the connecting high-strength

FIGURE 34.10 Prototypical forged ductile rod. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

bolts. The manufacture and distribution of the system is controlled by Dywidag Systems International under the name of Dywidag Ductile Connector (DDC®). System capacity is developed directly from accepted load transfer mechanisms and conditions of equilibrium. The strength reduction factors and overstrength factors are consistent with values used in the design of concrete ductile frames. The key element in the assembly described in Figure 34.9 is the ductile rod (Figure 34.10). This ductile rod is the yielding element. The function of the ductile rod is to accommodate post-yield system deformations.

Our analytic understanding of system behavior, then, logically starts from the ductile rod and moves first to the beam and then into the column. When a moment couple is developed between two sets of N rods separated by a distance $d - d'$ (Figure 34.11), the nominal moment capacity (M_n) developed is:

$$M_n = NT_y(d - d') \quad (34.6)$$

where T_y is the nominal tensile strength of one ductile rod. The nominal capacity of the set of ductile rods must be developed in the beam. Because the adopted design objective for the rest of the system is elastic behavior, an overstrength factor (λ_o) must be introduced.

The first load transfer point proceeding toward the beam is the beam–column interface, where the appropriate level of shear and moment must be transferred. High-strength (1-1/2-in. ϕ -A490SC) bolts are used to accomplish this transfer. The nominal tensile strength provided by this bolt is on the order of 210 kips, which exceeds the nominal tension strength of the ductile rod by more than 25%:

$$T_{bn} = \lambda_o \frac{M_n}{(d - d')}$$

$$NA_B = \frac{T_{bn}}{\phi F_t}$$

The shear load (V_{nE}) induced by the ductile rod mechanism at the beam-to-column interface is:

FIGURE 34.11 DDC® connection, shear transfer mechanism (friction: steel to steel). (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

$$V_{nE} = \frac{2\lambda_o M_n}{\ell_c}$$

where ℓ_c is the clear span of the beam. The nominal shear capacity required of the connector is:

$$V = V_{nE} + V_D + V_L \quad (34.7)$$

Comment: Because the design objective is code compliance, factored dead and live loads are appropriately used. Concerns relative to attaining shear transfer in the plastic hinge region of a cast-in-place frame beam ($V_c = 0$) do not apply because the plastic hinge region is no longer in the beam.

The shear transfer mechanism between beam and column is friction. The load proceeds from the face of the ductile rod to the beam transfer block (see Figure 34.11) through a set of shim plates that provide longitudinal tolerance. The normal load that activates this friction load path is the larger of the bolt pretension (T_p) or flexurally induced compression ($M/d - d'$). The ability of the connector described in Figure 34.11 to transfer load will depend on the level of pretensioning ($2NT_p$) and applied moment (M). The level of applied moment (M) must at some instant be zero. At this instant, both the upper and lower connections will participate in the transfer of shear. Accordingly,

$$V_D + V_L < 2NT_p f \quad (34.8)$$

where f is the friction factor allowed by the load and resistance factor design (LRFD) specifications.

As moment is applied to the connection, the effective level of pretensioning on the tensile bolt group will be relieved. Observe that the force applied to the ductile rods is unaffected by the level of bolt preload, for the bolts serve only to clamp the beam transfer block to the ductile rod. When the preload (NT_p) has been relieved, however, the ability of the compression face connector to transfer shear will continue to increase, for the compression (C) crossing the surface described in Figure 34.11 will now be entirely a function of the level of moment imposed on the connection. Hence, C will be the larger

FIGURE 34.12 DDC® connection, shear transfer mechanism (concrete bearing: confined region). (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

of NT_p or $(M/d - d')$. Accordingly, the nominal capacity of the shear transfer mechanism is the larger of these values:

$$V_n = \left(\frac{M}{(d - d')} \text{ or } NT_p \right) f \quad (34.9)$$

where f , the friction factor used, should be 0.35 when dead and live loads are the concern (Equation 34.8) or 0.5 when seismic limit state shears are considered (Equation 34.7) because a shear slip will not result in a system failure. Beam component design should logically proceed based on the adoption of a variable overstrength factor (λ_o). The required capacity of each element should be modified ($\lambda_o \phi$) to approximately account for uncertainties associated with each of the considered load transfer mechanisms.

The yield strength of Threadbars® (high-strength threaded bars manufactured by Dywidag) that extend into the beam (Figure 34.9) is guaranteed. The assembly has been tested to ensure that yielding does in fact occur exclusively in the ductile rod (Figure 34.10). Alternatives for connecting the Threadbars® in the beam include reverse threads in the transfer block, couplers, or splice bars. Shear reinforcement is developed from Equation 34.7, and high-strength shear reinforcement ($f_y = 75$ ksi) may also be used here because post-yield behavior in the stirrups is guarded against by the use of a capacity-based design. The load path from the ductile rod to the column is by bearing (Figure 34.12). Shear loads are equilibrated by bearing stresses under the compression side rod ends at the face of the column. The bearing stress allowed for confined concrete may appropriately be used because the shear load is only transferred through the compressed zone of the frame beam, and the shim plates provide a significant normal or confining pressure in this part of the column.

The internal bearing at the rod end when two rods abut (Figure 34.12) is subjected to a tensile load from the ductile rod on one side and a compressive load from the rod on the opposite side, at least until the post-yield strain imposed on the ductile rod has been recovered. The tensile load will at some point exceed T_{yi} , and the yield strength of the rod is accordingly factored to account for probable overstrength. The worst-case bearing load imposed on the anchor end of a ductile rod is $2\lambda_o T_{yi}$, but this will not be realized because any overstrength compression side demand will be resisted by bearing on the face of the column. The concrete within the core of the column that resists this load is well confined, and the supporting surface is wider than the bearing area on all sides. The design bearing stress may conservatively be presumed to be $0.85\phi(2)f'_c$, according to ACI 318-05, Section 10.17.1 (ACI Committee 318, 2005), and this is $1.2f'_c$.

A set of compressive struts distributes bearing stresses imposed on the rod ends to joint reinforcement located above, below, and alongside the ductile rod assembly (Figure 34.12). The internal load transfer

FIGURE 34.13 Precast concrete bracing tower. (Photograph courtesy of Englekirk Partners, Los Angeles, CA.)

mechanism within the joint itself, with the exception of the load transfer ties, is much the same as that which occurs in the panel zone of a concrete ductile frame. It is discussed in considerably more detail in Section 34.4. The bracing tower of Figure 34.13 was built using the DDC® system.

34.3.2 Post-Tensioned Assemblages

Post-tensioned assemblages consisting of precast beams and columns were first tested in the early 1970s. Early rejections of the concept were based on the fact that no energy was dissipated by the system and a concern that anchorage systems would fail. In the 1990s, these problems were overcome with the development of what is now referred to as the *hybrid system* (Cheok and Lew, 1993; Englekirk, 2003). The system was then used to construct the building shown in Figure 34.14. A comprehensive test program in support of the design of this building was conducted by Professor Stanton at the University of Washington. The exterior subassembly shown in Figure 34.15 describes the post-yield behavior of the beam for the capacity of the column, and the joint in the subassembly significantly exceeds the demand imposed on them by the beam. The fact that post-yield deformation occurred almost exclusively in the beam was confirmed by the test program.

Flexural strength in the hybrid beam (Figure 34.16) is provided by a combination of unbonded post-tensioning strands and bonded mild steel. Nine 1/2-in. 270-ksi strands stressed to 162 ksi were used in the system described in Figure 34.15 to provide an effective concentric post-tensioning force of 223.1 kips. Three #6 (GR60) reinforcing bars were placed in the top and bottom of the beam in tubes that were subsequently grouted with high-strength grout. These bars provide energy dissipation, an attribute not provided by the unbonded post-tensioning. The strength provided by the 16 × 21-in.-deep beam is defined by the size of the grout pad, which for this test was 16 × 20 in.

The design of the exterior subassembly of Figure 34.15 assumed that the stress in the mild steel compression reinforcement reached yield. Accordingly, the flexural strength provided by the mild steel (M_{ns}) was:

$$M_{ns} = T_{ns}(d - d') = 3(0.44)(60)(16.5) = 1307 \text{ in.-kips} \quad (34.10)$$

The flexural strength provided by the unbonded post-tensioning (M_{nps}) is developed as follows (see Figure 34.16):

FIGURE 34.14 Paramount Apartments, San Francisco, CA. (Photograph courtesy of David Wakely Photography, San Francisco, CA.)

$$T_{nps} = A_{ps} f_{pse}$$

$$T_{nps} = 9(0.153)(162) = 223.1 \text{ kips} \quad (34.11a)$$

$$a = \frac{T_{nps}}{0.85 f'_c b} = \frac{223.1}{0.85(5)(16)} = 3.3 \text{ in.}$$

$$M_{nps} = T_{nps} \left(\frac{h}{2} - \frac{a}{2} \right) = 223.1(10 - 1.65) = 1865 \text{ in.-kips} \quad (34.11b)$$

The nominal moment capacity of the hybrid frame beam of Figure 34.15 is:

$$M_n = M_{ns} + M_{nps} = 1307 + 1865 = 3172 \text{ in.-kips} \quad (34.12)$$

This corresponds to a beam load or shear of:

$$V_{nb} = \frac{M_n}{\ell_c} = \frac{3172}{62} = 51.2 \text{ kips}$$

The associated column shear or applied test frame force (F_{col}) is:

$$V_c = F_{col} = V_{nb} \left(\frac{\ell}{h_x} \right) = 51.2 \left(\frac{72}{117.5} \right) = 31.4 \text{ kips}$$

FIGURE 34.15 Exterior subassembly. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

FIGURE 34.16 Beam and column cross-sections, hybrid subassembly test program. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

Figure 34.17a describes the behavior of the test specimen. Figure 34.17b identifies critical behavior milestones. The stresses imposed on the post-tensioning strands are shown in Figure 34.18, where they are related to test specimen drift. Observe that the predicted nominal strength of 31.4 kips (V_c) is not

(a) Full Hysteretic Behavior

Mark	Event	Set	Drift Ratio
A	Grout cracking interface	4	0.10
B	Grout lift-off interface	5	0.15
C	Surface cracking joint	5	0.15
D	Surface cracking beam	6	0.20
E	Bar yield, continuity bar	10	0.75
F	Bar fracture, continuity bar	17	4.0
G	Concrete spalling-beam	16	3.5

(b) Critical Behavior Milestones

FIGURE 34.17 Test specimen behavior. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

reached until a drift ratio of almost 2% is attained (Figure 34.17b). This is at least in part explained by the fact that the initially delivered post-tensioning force was only 216 kips, or 4% less than the specified 223.1 kips. A story drift of 1% was required to develop the assumed design force in the post-tensioning ($T_{nps} = 223.1$ kips).

Subassembly stiffness as predicted by idealized member stiffness is developed as follows (Englekirk, 2003):

FIGURE 34.18 Post-tensioning (PT) force vs. drift relationship. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

$$\Delta_x = \frac{V_c h_x^2}{6E} \left(\frac{\ell}{I_b} + \frac{h_x}{2I_c} \right)$$

$$h_x = 117.5 \text{ in.}$$

$$\ell = 72 \text{ in.}$$

$$I_{ce} = 0.71 I_g = \frac{0.7(18)(20)^3}{12} = 8400 \text{ in.}^4$$

$$I_{be} = 0.35 I_g = \frac{0.35(16)(21)^3}{12} = 4322 \text{ in.}^4$$

$$\Delta_x = \frac{31.4(117.5)^2}{6(4000)} \left[\frac{72}{4322} + \frac{117.5}{8400} \right] = 0.55 \text{ in.}$$

The associated drift ratio (Δ/h_x) is 0.47%. This drift ratio might be accepted as an idealized representation of stiffness to a column shear of about 50% of the nominal column shear (31.4 kips) but not as a good idealization for the behavior described in Figure 34.17. The hybrid subassembly appears to be considerably softer than a cast-in-place system (Englekirk, 2003).

Probable flexural strength and ultimate strain states should be predicted during the system analysis phase, as opposed to the conceptual design phase of the project. The process begins by estimating the strain states in the reinforcing at a selected level of drift. Consider a 4% post-yield drift ratio (θ_p), our objective drift, and realize that any elastic component of story drift will be small (Figure 34.17). The plastic hinge length (ℓ_p) initially will be the debonded length of the mild steel, in this case 6 in.:

$$\theta_y = \phi_y \ell_p = \left(\frac{0.002}{h-c} \right) (6) = \left(\frac{0.002}{20-4} \right) (6) \cong 0.00075 \text{ radian}$$

Further, assume that all of the post-yield rotation will occur at the beam–column interface (Figure 34.6). The elongations of the tensile reinforcement components, (δ_p and δ_s) are best made using an iterative process, for the stress levels in the reinforcement will dictate the location of the neutral axis. Begin the iterative process by assuming a neutral axis depth (c) of 6 in.:

$$c = 6 \text{ in.}$$

$$\delta_s = (d-c)\theta_p = (18.25-6)(0.04) = 0.49 \text{ in.}$$

The intentional mild steel debond length (Figure 34.15) was 6 in. but can reasonably be expanded to include some adjacent debonding. Hence, the effective debond length (ℓ_d) is on the order of:

$$\ell_d = 6 + 2(d_b) = 7.5 \text{ in.}$$

and the post-yield strain state in the debond region (ϵ_{sp}) is:

$$\epsilon_{sp} = \frac{\delta_s}{\ell_d} = \frac{0.49}{7.5} = 0.065 \text{ in./in.}$$

This corresponds to a stress in the bar of (Englekirk, 2003):

$$\lambda_o f_y \cong 86 \text{ ksi}$$

The elongation of the post-tensioning strand (δ_{psp}) is:

$$\delta_{psp} = \left(\frac{h}{2} - c \right) \theta_p = (10-6)0.04 = 0.16 \text{ in.}$$

The overall length of the strand (Figure 34.15) is on the order of 100 in.; hence,

$$\Delta \epsilon_{psp} = \frac{0.16}{100} = 0.0016 \text{ in./in.}$$

$$\Delta f_{ps} = \Delta \epsilon_{psp} E_{ps} = 0.0016(28,000) = 45 \text{ ksi}$$

$$f_{ps} = f_{se} + \Delta f_{psp} = 162 + 45 = 207 \text{ ksi} < f_{py} \cong 230 \text{ ksi}$$

The total tensile force in the post-tensioning steel at a joint rotation (θ_p) of 0.04 radian is (theoretical):

$$\Delta T_{ps} = A_{sp} \Delta f_{psp} = 9(0.153)45 = 61.7 \text{ kips}$$

$$T_{ps} = 223.1 + 61.7 = 286 \text{ kips}$$

Comment: Observe that the projected force in the post-tensioning is consistent with that measured (on the positive cycle) at a drift angle of 4% (Figure 34.18).

The tensile force provided by the mild reinforcing is:

$$T_s = 3(0.44)(86) = 114 \text{ kips}$$

The depth to the neutral axis may now be estimated:

$$T_{ps} + T_s - C_{sy} = 286 + 114 - 79 = 320 \text{ kips}$$

$$a = \frac{320}{0.85(5)(16)} = 4.7 \text{ in.}$$

$$c = \frac{a}{0.8} = 5.9 \text{ in.}$$

Conclusion: A neutral axis depth of 6 in. was reasonably presumed.

Strain levels in the concrete are quite high. If we assume a plastic hinge length (ℓ_p) equivalent to the debond length (ℓ_d):

$$\phi_p = \frac{\theta_p - \theta_y}{\ell_p} = \frac{0.0392}{7.5} = 0.0052 \text{ rad./in.}$$

$$\epsilon_c = \phi_p c = 0.0052(6) = 0.031 \text{ in./in.} \quad (34.13)$$

$$\epsilon_s = \phi_p (d - c) = 0.0052(12.25) = 0.064 \text{ in./in.}$$

It was for this reason that the developers of the hybrid system armored beam corners with angles during the NIST tests (Cheok and Lew, 1993). The University of Washington test specimens were not armored. Beam corners did exhibit surface cracking early, but beam strength did not begin to deteriorate until drifts exceeded 4% (see Figure 34.17b). The plasticity of high-strength grout probably absorbs a disproportionate amount of the post-yield concrete strain because these grouts are usually quite ductile.

Comment: The fact that one of the mild steel bars fractured at a drift angle of 2.5% is disconcerting because the apparent strain in this bar is below that normally associated with fracture. Seven identical beams were tested, and this bar was the only one that fractured. A conservative selection of the debond length based on a fracture strain of 5% is suggested.

The probable moment capacity (M_{pr}) at a drift angle of 4% discounting the ruptured #6 bar is:

$$\begin{aligned} M_{pr} &= T_{ns} \left(d - d' \right) + T_{ps} \left(\frac{h}{2} - \frac{a}{2} \right) + (T_s - T_{ns}) \left(d - \frac{a}{2} \right) \\ &= 52.8(16.5) + 286(10 - 2.35) + 35(18.25 - 2.35) = 871 + 2188 + 373 = 3432 \text{ in.-kips} \end{aligned} \quad (34.14)$$

This corresponds to a column shear force of:

$$V_{c,pr} = M_{pr} \left(\frac{\ell}{\ell_c} \right) \left(\frac{1}{h} \right) = 3432 \left(\frac{72}{62} \right) \left(\frac{1}{117.5} \right) = 34.7 \text{ kips}$$

This predicted column shear force is consistent with the test results (Figure 34.17).

34.3.3 Interior Beam–Column Joints

34.3.3.1 Post-Tensioned Assemblies (Hybrid System)

Joint shear stress analysis procedures are developed as they are for conventionally reinforced cast-in-place concrete beam–column joints. The shear imposed on the beam–column joint ($V_{jh,prob}$) is shown in Figure 34.19:

$$V_{jh,prob} = \lambda_o T_{nps} + 2\lambda_o T_s - V_c$$

FIGURE 34.19 Forces acting on a hybrid beam–column joint. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

And the shear stress imposed on the joint ($v_{jh,prob}$) is:

$$v_{jh,prob} = \frac{V_{jh,prob}}{A_j}$$

where A_j is the gross area of the column. The allowable joint shear stress ($v_{jh,allow}$) is:

$$v_{jh,allow} = 15\phi\sqrt{f'_c}$$

34.3.3.2 Bolted Assemblies (DDC®)

Joint shear stress analysis follows those procedures adopted for cast-in-place concrete (Figure 34.20). The discontinuity between ductile rods may be handled in a variety of ways, as it increases the ability of the joint to transfer loads (Englekirk, 2003). The test specimen followed the load flow described in Figure 34.20 where the tension rod (DR1) activates the proximate tie sets, which then deliver it to the compression node. Alternatively, an interior node may be presumed at the rod heads. Given this alternative, an ℓ_c secondary strut and tie transfer will be developed, and this undoubtedly accounts for the superior performance of the DDC® beam–column joint (to drift ratios of 6%). Joint shear stress analysis procedures are conservatively developed, as they are for conventionally reinforced cast-in-place concrete beam–column joints.

34.4 The Conceptual Design Process

The process described herein is intended to provide the development team with enough data to make an informed decision regarding the appropriateness of alternative systems. The design process, in conjunction with the constructor, must create alternative solutions using these generic approaches as points of departure.

34.4.1 Bolted Systems

The approach described specifically utilizes the Dywidag Ductile Connector (DDC®) system, which is controlled by patents. This control of product is important because many subtle quality-control design issues are dealt with in the product provided; these include a fail-proof bolt setting length as well as system tolerances and ductility. The design process begins with development of the seismic-induced shear loads that the bracing system must sustain. The major system constraint lies in the fact that one assembly (two ductile rods) has a relatively high yield strength, and this strength cannot be fine tuned. This

FIGURE 34.20 Load flow within a DDC® beam-column joint. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

constraint must be considered very early in the design process and the bracing program modified to accommodate system and functional objectives. The assembly described in Figure 34.9 contains two ductile rods, which establish its yield strength at about 300 kips (T_n), and this sets the strength increments.

The basic geometry of the building bracing program has been established: column spacing and story height; thus, given a story shear, the first question to be addressed is the number of frame bays required. The process must be reduced to its simplest form, and this means discounting compensating factors; for example, building torsion will increase the demand on some components, while using center-line dimensions will understate the capacity of a subassembly (they usually counterbalance each other). Hence,

$$V = \frac{2nM_u}{h_x} \quad (34.15)$$

where V is the objective base shear for the building (kips); n is the number of frame bays; M_u is the factored moment capacity of the frame beam (ft-kips); and h_x is the story height (ft).

• *Step 1: Determine the number of frames required.*

$$V = 2000 \text{ kips}$$

$$h_x = 11 \text{ ft}$$

$$M_u = 900 \text{ ft-kips (1-DDC; } d - d' = 3.33 \text{ ft)}$$

$$n = \frac{2000(11)}{900} = 24$$

Conclusions: 24 assemblies of the type described in Figure 34.9 are required. Two assemblies per beam seems most logical. System proposed should be 12 frame bays in each direction, two DDC®s per beam.

Comment: The number of required frame bays may be significantly reduced by combining the bolted and hybrid systems.

- *Step 2: Size and detail the beam.*

$$b = 30 \text{ in.}, h = 46 \text{ in.}, 2 \text{ DDC}^{\circledR} \text{ assemblies per beam (see Figure 34.9)}$$

- *Step 3: Check beam–column joint shear.*

Use procedures adopted by ACI, replacing $\lambda_o f_y A_s$ and $\lambda_o f_y A'_s$ with $\lambda_o n T_y$, where n is the number of DDC[®] assemblies, and T_y is the yield strength of one assembly (two rods \cong 300 kips).

- *Step 4: Proceed to develop the system load path as appropriate for a cast-in-place system using a capacity-based design approach.*

34.4.2 Post-Tensioned Systems

Given that the capacity of a hybrid system can be changed quite readily, the number of frames required is usually more closely related to building geometry, constructability, and function. The size of the beams and their grouping will tend to control the design process. When the objective beam size has been established, the developable strength is established and from this the bracing program for the building created.

- *Step 1: Determine a trial reinforcing program.*

It is advisable to maintain a reasonable level of restoring force, for this is clearly a very positive attribute of post-tensioning. Accordingly, a design objective should be to provide at least 50% of the moment capacity with the post-tensioning. Begin by selecting the appropriate level of mild steel reinforcing:

$$M_{us} \cong 0.4M_u$$

$$A_s = \frac{0.4M_u}{\phi f_y (d - d')}$$

Then determine the amount of post-tensioning steel required to satisfy the strength objectives:

$$M_{ups} = M_u - 0.9f_y (d - d') A_s \quad (34.16)$$

$$A_{ps} = \frac{M_{ups}}{\phi f_{ps} \left(\frac{h}{2} - \frac{a}{2} \right)} \quad (34.17)$$

where f_{ps} may be conservatively assumed to be the effective level of prestress, usually 162 ksi.

Comment: A nominal strength projection based on an effective prestress of 162 ksi will result in a strength equivalent to about 95% of its nominal strength, but this seems reasonable given the softness of the system (Figure 34.17).

- *Step 2: Determine the minimum size of the beam–column joint.*

The analysis procedure for the hybrid beam system is developed in Section 34.3.3. An approximate relationship between the area of the beam–column joint and the amount of beam reinforcing is developed in Englekirk (2003):

$$A_j = 62(A_s + A'_s) + 210A_{ps} \quad (34.18)$$

- *Step 3: Check the feasibility of placing the reinforcement suggested by the trial design.*
- *Step 4: Check to ensure that the provided level of post-tensioning is reasonable, on the order of 1000 psi.*

Comment: The hybrid beam will become an integral part of the floor system. Large stress differentials may cause undesirable cracking in unstressed floors. Accordingly, it is best to use 1000 psi as an objective prestress limit.

• *Step 5: Check the shear capacity/demand ratio to ensure that objective shear stress limit states have not been exceeded:*

$$V_b = \frac{2\lambda_o(M_{ns} + M_{nps})}{\ell_c} + V_D + V_L \quad (34.19)$$

where V_D and V_L are the dead and live load shears, respectively, and ℓ_c is the clear span of the beam.

Comment: Sufficient accuracy for design purposes may be attained through the use of an overstrength factor (λ_o) of 1.25:

$$bd \geq \frac{V_b}{5\sqrt{f'_c}}$$

Remember that, in this case, because the adopted limit state ($5\sqrt{f'_c}$) is less than that proposed in most codes, V_D and V_L should be realistically selected, not the factored loads used in a code-compliance analysis. This limit state is perhaps somewhat conservatively applied to the hybrid system because the hinge deformation tends to accumulate at the joining of the beam and the column (see Figure 34.6) and the plastic hinge region is prestressed.

• *Step 6: Check column shear if the beam is deep and the column short.*

For an exterior subassembly (Figure 34.15) this is:

$$b_c h_c \geq \frac{\lambda_o(M_{ns} + M_{nps})}{5\sqrt{f'_c} h_x} \geq \frac{3.6(M_{ns} + M_{nps})}{h_x}$$

Design Example

Design a 20 × 32-in. hybrid interior beam for the described subassembly:

$$V_{cu} = 200 \text{ kips (column shear)}$$

$$\ell_1 = 24 \text{ ft}; \ell_{c1} = 21 \text{ ft}$$

$$\ell_2 = 16 \text{ ft}; \ell_{c2} = 13 \text{ ft}$$

$$h_x = 9 \text{ ft}$$

• *Step 1: Select a trial beam reinforcement program.*

$$V_c h_x = M_{bu} \left(\frac{\ell_1}{\ell_{c1}} + \frac{\ell_2}{\ell_{c2}} \right)$$

For an interior column and an objective column shear of 200 kips,

$$M_{bu} = \frac{V_c h_x}{\left(\frac{\ell_1}{\ell_{c1}} + \frac{\ell_2}{\ell_{c2}} \right)} = \frac{200(9)}{1.14 + 1.23} = 760 \text{ ft-kips}$$

Select a mild steel reinforcing program:

$$M_{us} = 0.4M_{bu} = 0.4(760) = 304 \text{ ft-kips}$$

$$A_s = \frac{M_{us}}{\phi f_y (d - d')} = \frac{304(12)}{0.9(60)(29 - 3)} = 2.6 \text{ in.}^2$$

Try three #9 bars. Select the post-tensioning reinforcement:

$$M_{us} = A_s \phi f_y (d - d') = 3.0(0.9)(60)(29 - 3) = 4212 \text{ in.-kips} \quad (M_{ns} = 4680 \text{ in.-kips})$$

$$\phi M_{nps} = M_{bu} - M_{us} = 760(12) - 4212 = 4908 \text{ in.-kips} > 4212 \text{ in.-kips} \quad (\text{OK})$$

Accordingly, the flexural strength provided by the post-tensioning exceeds that provided by the mild steel, and this was identified as a design objective. For design purposes the nominal strength of unbonded strands (f_{pn}) is assumed to be its effective strength:

$$f_{pn} = f_{pse}$$

Comment: The development of f_{pn} in ACI 318-05 (f_{ps} , Equation 18-5) is based on a correlation between test data and analysis. Observe that a similar relationship ($f_{pse} + 10,000$) between effective and nominal strength is not appropriate for the hybrid system. The tensile force in the tendon corresponding to a strand stress of 162 ksi in the test described in Figure 34.18 would be 223 kips, and this force is not developed until the drift reaches 1.5%. Accordingly, the use of f_{pse} to define the nominal strength of a hybrid beam is viewed as being appropriate:

$$A_{ps} = \frac{\phi M_{nps}}{\phi f_{pse} \left(\frac{h}{2} - \frac{a}{2} \right)} = \frac{4908}{0.9(162)(16 - 3)}$$

where the depth of the compressive stress block (a) is presumed to be about 6 in.

$$A_{ps} = 2.59 \text{ in.}^2$$

Use 0.6-in. \emptyset strands ($A = 0.217 \text{ in.}^2$).

Comment: 0.6-in. \emptyset strand hardware is most common in the United States but local availability should be confirmed.

$$\text{Number of strands required} = 2.59/0.217 = 11.9$$

Check the level of prestress provided by 12 strands:

$$f_c = \frac{12(0.217)(162)}{20(32)} = 0.660 \text{ ksi} \quad (\text{OK})$$

Conclusion: The trial reinforcing program will consist of 12 0.6-in.-diameter strands and 3 #9 (GR 60) reinforcing bars, top and bottom. The nominal strength of this beam is:

$$M_n = M_{nps} + M_{ns}$$

$$a = \frac{T_{ps}}{0.85 f'_c b} = \frac{12(0.217)}{0.85(5)(20)} = 5 \text{ in.}$$

$$M_{nps} = T_{nps} \left(\frac{h}{2} - \frac{a}{2} \right) = 422(16 - 2.5) = 5697 \text{ in.-kips}$$

$$\phi M_n = 9340 \text{ in.-kips} > 9310 \text{ in.-kips} \quad (\text{OK})$$

FIGURE 34.21 Hybrid beam reinforcement program. (From Englekirk, R.E., *Reinforced and Precast Concrete Buildings*, John Wiley & Sons, New York, 2003. Reprinted with permission of John Wiley & Sons, Inc.)

- *Step 2: Determine minimum size of the beam–column joint.*

$$A_i = 62(A_s + A'_s) + 210A_{ps} = 62(6) + 210(12)(0.217) = 919 \text{ in}^2$$

Conclusion: Column size should be at least 30×32 in.

- *Step 3: Develop the beam and column reinforcing program.*

The mild steel must be placed in ducts and grouted. The post-tensioning strands will also be placed in a duct and stressed using a multistrand jack. Mild steel tubes should have a diameter of at least $2d_s$. The post-tensioning duct will be of the size suggested by the supplier. Column bars will have to be placed in this central region, and they must pass the post-tensioning duct and yet be inside the outer mild steel duct (see Figure 34.21). Beam bars cast in the corners of the precast beam are also required if for no other reason than to reinforce an otherwise unreinforced region. Minimum flexural reinforcing requirements are usually satisfied by the post-tensioning, so the basis for the sizing of these bars depends on the designer's convictions relative to splicing concerns. ACI 318-05, Section 18.9, requires a minimum amount of bonded reinforcement in all flexural members with unbonded prestressing tendons:

$$A_{s,min} = 0.004A_{ct}$$

where A_{ci} is the area between the tension face and the center of gravity of the gross section. The beam-sizing process must then allow for the flexural reinforcing provided in the precast beam as well as the space that may be required to pass the column bars (see Figure 34.21). The minimum beam width becomes:

One post-tensioning duct	3.50 in.
Two #11 column bars	2.75 in.
Two mild steel ducts	4.50 in.
Two corner bar diameters	2.00 in.
Two corner bars	2.00 in.
#5 hoop ties	1.25 in.
Fire cover	3.00 in.
Total	19.00 in.

Conclusion: The minimum beam width should be 20 in.

The minimum bonded reinforcement (ACI 318-05, Equation 18-6) is:

$$A_{s,\min} = 0.004b \frac{h}{2} = 0.004(20)16 = 1.28 \text{ in.}^2$$

Conclusion: The beam should be 20 in. wide. At least one #8 bar should be provided in each corner.

Comment: This mild steel may have to be increased to reduce concrete cracking during transportation, but this will be the concern of the fabricator.

34.5 Concluding Remarks

The design of precast systems does not require special knowledge, for it follows principles used by structural engineers to design ductile moment resisting frame systems. A more detailed development of both cast-in-place and precast systems is contained in *Seismic Design of Reinforced and Precast Concrete Buildings* (Englekirk, 2003). The designer of precast frame systems is encouraged to be creative in the development of systems. The combining of the DDC® system with the hybrid system is but one example. The design–build delivery system lends itself to creative solutions, but both the hybrid and DDC systems have been constructed using the traditional design–bid–build delivery system.

35.1 Overview of Crack Mitigation

When selecting the concrete configuration and reinforcement layout for a concrete building, the engineer typically considers strength requirements and then addresses serviceability concerns. During the serviceability check, attention is directed to deflection and durability, but many times detailing for serviceability to mitigate cracking is overlooked. Cracking in reinforced concrete buildings can be addressed early in the design process through judicious consideration of building layout, selection of appropriate connections, and use of appropriate reinforcement detailing. It is advisable to evaluate during the member design stage those members within a structure that may be subject to various types of cracks. Predicting possible crack behavior or crack development among members within a building typically allows application of appropriate mitigating detailing. Whether cracking is caused by restrained shortening of concrete or cross-sectional action, effective detailing of concrete members can significantly impact the long-term performance and durability of the concrete structure.

* President, American Concrete Institute, and Principal Consultant, FBA, Inc., Hayward, California; expert in analysis, design, evaluation, and retrofit of post-tensioned concrete structures.

The intent of this chapter is to provide a basic understanding of crack development as well as design detailing recommendations to mitigate cracking in concrete members. It specifically excludes the review of concrete member cracking due to unique or special materials used or the preparation (mix properties/proportions), placing, and conditioning of poured concrete. The design details presented herein are limited to building structures; special structures and non-building structures are not part of this review. This chapter is limited to cast-in-place concrete frames only; precast concrete and masonry elements are excluded. Post-tensioned concrete floor systems have become the predominate choice for concrete floor systems using cast-in-place construction. For this reason, examples within this chapter focus on post-tensioned concrete floor systems when evaluating crack mitigation, as such slabs have an added elastic shortening component and concrete creep to address due to the precompressed concrete cross-section.

Many publications offer a summary of standard details for the construction of concrete structures; however, it is a challenge to find documentation of appropriate or standard detailing to aid the designer in addressing concrete cracking. This chapter, however, aims to address the overall nature of a structure and how members may experience tensile stresses due to the restraint or other cross-sectional actions resulting in tension beyond the concrete modulus of rupture.

The first objective is to capture framing conditions where the crack development of a concrete member is directly or indirectly affected by the behavior of the neighboring elements or the overall framing system and to suggest detailing to avoid or minimize such cracking. Much of the information presented has been adapted from the work by Aalami and Barth (1988).

35.2 Member Selection

Member shape and frame compatibility are the basic foundations of a performing structure. An example of framing incompatibility would be found in a structure where concrete member sizes or strength requirements are simply out of scale. This can be the case when oversized architectural columns are used to support a thin slab. The restraining effects of oversized members on the surrounding members can be significant. For this reason, it is advisable to maintain compatible member sizes and connections to mitigate restraint cracking during concrete shortening. If geometry or architectural considerations dictate such incompatibility, special consideration should be given to incompatible member connections. Alternatively, incompatible framing geometry can also be addressed using built-up foam sections after the concrete frame is completed to achieve the architectural shapes desired. Frequently, new materials are introduced, whether as composite construction or simply performance-enhancing additives to the concrete mix. The resulting alteration in shortening effects must be understood. For composite construction, such as pan-filled metal decks, construction layout and long-term shortening effects should be evaluated. An important serviceability aspect of concrete material and mixture proportions selection is the resulting shortening behavior for the particular application and geometry.

35.3 Crack Causes and Types

Several factors, when combined, can lead to restraint cracks in two-way reinforced-concrete slabs. Concrete slabs tend to shorten, and structurally stiff elements such as walls, elevator and stairwell cores, and columns can restrain the slab. When the tensile stress exceeds the tensile strength of the concrete, a restraint crack occurs (ACI Committee 224, 1997). Depending on many factors, including the stiffness of the restraining elements and the length of the slab spans, multiple restraint shrinkage cracks may form. The specific factors that cause shortening of concrete slabs include:

- Shrinkage of concrete
- Creep of concrete due to sustained loads (including precompression)
- Elastic shortening (prestressed slabs only)
- Fall in temperature

FIGURE 35.1 Factors contributing to slab shortening.

TABLE 35.1 Contribution of Various Factors to Typical Slab Shortening for Parking Structure in California

Factor	Percentage
Shrinkage	66
Creep	11
Elastic Shortening	7
Temperature	16
Total	100

For a typical parking structure in Southern California with 70% ambient humidity and a moderate temperature variation of 40°F, the contributions of the above factors to slab shortening are as given in Figure 35.1 and Table 35.1. It is noteworthy that two thirds of slab shortening is typically due to concrete shrinkage. Axial creep and elastic shortening, which are the only direct consequences of post-tensioning, contribute about one sixth of the total shortening.

To appreciate the magnitude of shortenings that are likely to occur in a post-tensioned slab, consider the example shown in Figure 35.2. For the 200 × 100-ft slab shown, the shortenings (if free to take place) are estimated to be 0.8 in. per 100 ft of slab length. Obviously, this shortening cannot materialize in most cases, because the slabs are commonly tied to supporting structural elements. The interaction of the slab with its restraining structural elements is the crucial factor in the formation of cracks. Referring to the breakdown of shortenings in Figure 35.2, only 18% of the calculated shortening is due to post-tensioning. The balance is common to nonprestressed as well as post-tensioned slabs. This shows that little difference exists between post-tensioned and nonprestressed slabs as far as crack initiation is concerned; however, crack propagation is fundamentally different between the two types of slabs.

FIGURE 35.2 Reflected ceiling view of slabs: (a) post-tensioned slab; (b) reinforced concrete slab.

Prominent characteristics of cracks in unbonded post-tensioned slabs as compared to regular reinforced concrete are the following:

- Cracks are fewer in number; instead of a multitude of hairline cracks, fewer cracks form.
- Cracks are generally wider; they are spaced farther apart and generally extend deeper into the slab. In regular reinforced concrete, the spacing between cracks is of the order of slab depth, whereas in post-tensioned slabs it is more related to the span length and the overall dimensions of the slabs. In most cases, crack spacing is more than one quarter of the shorter slab span.
- Cracks are normally longer and continuous, and continuous cracks may extend over one span and beyond. In nonprestressed concrete, cracks are generally shorter in length.
- Cracks commonly do not coincide with locations of maximum moments. Restraining cracks do not necessarily develop at the bottom of midspan or the top of supports where the bending moments are maximum.
- Cracks occur at axially weak locations. Axially weak regions are typically found at construction joints, pour strips, cold joints, paths with reduced discontinuities in slab, and, finally, where precompression is reduced either due to termination of tendons or friction losses in tendons. Figure 35.2 compares typical crack patterns on the soffit of an interior panel of a two-way slab construction. For the regular reinforced-concrete structure, the shrinkage cracks are shown coinciding with the locations of maximum tension.

Unbonded post-tensioned slabs generally exhibit poorer cracking performance as a result of lesser bonded reinforcement, which mobilizes the concrete in the immediate vicinity of a crack. Hence, a series of large slab segments separated by wide cracks rather than well-distributed small cracks is produced unless either the unbonded post-tensioning is accompanied by a sufficient nonprestressed reinforcement or in-plane restraining actions are present that result in a similar improvement of the crack distribution. Examples of common cracks in slabs, columns, and walls due to restrained movement are illustrated below.

Due to the variety of member types and geometry and the array of crack initiation factors, it is imperative that each concrete member be reviewed individually and as part of the overall framing system during the design detailing process. Concentrated load application and vulnerable member joint conditions may require a very localized review of concrete detailing. On the other hand, the overall framing layout may cause indirect load transfer due to geometry or member incompatibility, resulting in concrete cracking based on overall behavior of the framing system. This chapter allows for a localized and overall performance review.

35.3.1 Slab Cracks

With regard to the overall crack behavior of a two-way slab, Figure 35.3 shows the crack formation in one of many similar slab conditions investigated by the authors. The example is representative of many slabs having similar crack patterns. The slab is post-tensioned in both directions and designed as a two-way system according to Chapter 18 of ACI 318 (ACI Committee 318, 2005). The precompression provided by the tendons in the longitudinal direction is dissipated into the supporting walls, as the primary transverse cracks extend across the entire width of the slab and through its thickness. The layout in Figure 35.3 demonstrates that the prime cause of cracks is the restraining effect of the perimeter walls. In a slab that is free to move, such as that illustrated in Figure 35.4a, the tendon force (F) is balanced by the precompression developed in the slab. If the slab movement (shortening) is restrained through stiff walls or columns, such as the walls in Figure 35.4b, a part of tendon force F is diverted to the supporting elements. One other major source of overall slab cracks is irregularities in slab geometry. Typical examples of irregularities occurring in slabs are shown in Figure 35.5. If not properly detailed, the discontinuities at the reentrant corners invariably lead to cracks that may extend as far as one quarter to one third of the shorter width at the location of crack. Figure 35.6 shows examples of localized cracks in post-tensioned slabs. The illustrated cracks normally initiate within the first few days after concrete is placed and before the application of post-tensioning.

FIGURE 35.5 Irregular slab plans showing crack formation.

FIGURE 35.6 (a) Cracks at slab corners tied to corner walls; (b) crack formation at corners of interior openings.

35.3.2 Column Cracks

Short columns at split levels in parking structures, as illustrated in Figure 35.7, can develop severe cracks and spalling of concrete due to shortening of the parking decks immediately above and below. The same figure shows a release detail with a central dowel for prevention of such cracks. For simplicity, the stirrups in the short column are not shown. Columns tied to half-height walls, as shown in Figure 35.8a, develop cracks similar to those in the short columns described in Figure 35.7. The crack formation is especially severe in beam–slab floor constructions. Provisions of full-height or half-height joints between the walls

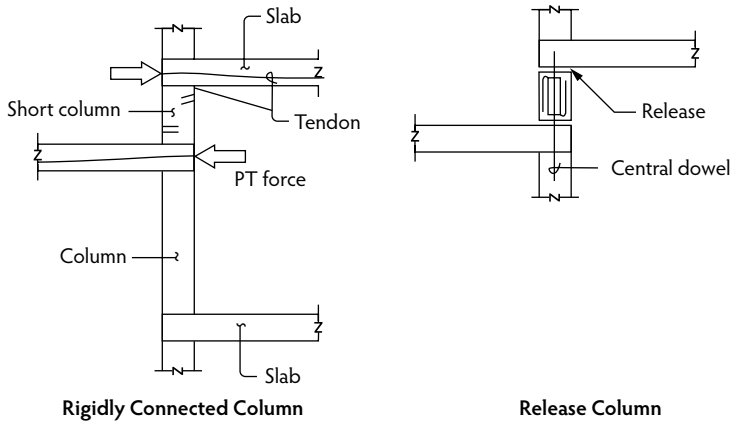

FIGURE 35.7 Cracking in short column at split level of parking structure.

FIGURE 35.8 Wall-column release: (a) side view of column tied to wall; (b) front view.

FIGURE 35.9 Cracks in end columns of long buildings.

and the columns, illustrated in Figure 35.8, are effective methods of mitigating such cracks. End columns of slabs 150 ft or more in length are particularly susceptible to cracks of the type illustrated in Figure 35.9. The moment generated in the column due to this displacement should be accounted for in the design of such columns.

35.3.3 Wall Cracks

Figure 35.10 illustrates the most common crack formation due to the overall behavior of walls tied to post-tensioned slabs. The diagonal tension cracks shown form at the ends of the walls due to the movement of the slab and extend over a region having a length of approximately one to two wall heights from the wall end. Such cracks can be reduced or eliminated by design.

FIGURE 35.10 Cracks in wall due to slab movement.

FIGURE 35.11 Planning in layout of shear walls to mitigate slab crack: (a) favorable arrangement of restraining walls; (b) unfavorable arrangement of restraining walls.

35.4 Crack Mitigation Measures

The principle techniques of crack mitigation are described in the following sections.

35.4.1 Planning the Layout of Restraining Members

The most effective method of restraint-crack prevention is the good selection of wall and column locations during the architectural planning of the building. Equal numbers and lengths of walls may be positioned so as to reduce the tendency of crack formation by allowing the slab to move freely toward a planned point of zero movement (Figure 35.11a). Figure 35.11b shows examples of unfavorably arranged walls and layouts in which the walls impede the free movement, thus creating conditions conducive to crack formation.

35.4.2 Structural Separation

Slabs of irregular geometry are particularly susceptible to cracking. Figure 35.12a shows a small slab area appended to a larger rectangular-shaped region. The structural separation shown in the figure between the two post-tensioned slabs consists of a physical gap between the slabs equal to 0.5 to 1 in. For the particular example shown, it is advisable to continue the slab separation through the supporting walls. The major difference between such structural separations and expansion joints is that the structural separation discussed herein loses its significance after a period of 2 to 3 months, during which time the bulk of the slab shortening takes place. The structural separation does not have to be designed to remain serviceable during the lifetime of the structure. An expansion joint that has been designed to accommodate temperature-induced movements must be detailed to remain operational during the in-service life of the structure. Smaller areas separated by openings or irregular slab geometries, such as the appendix shown in the top right corner of Figure 35.12b, cannot generally follow the overall pattern of shortening

FIGURE 35.12 (a) Separation between large areas forming an irregular shape; (b) separation between a large area and a small appendix.

of the entire slab area. Their connection to the main slab is primarily over short lengths. Stairwells, elevator shafts, and other walls impart substantial restraint against free movement of small slab areas. Moreover, in most cases, it is neither economical nor practical to effectively post-tension small slab areas less than 20 ft in length. The author's practice has been to provide a separation between the two slab areas and construct the detached smaller region as a nonprestressed slab. The structural separation for such conditions need not extend through the supporting walls. Typically, the separation is achieved by placing Styrofoam™ sheets, 0.5 to 0.75 in. thick, vertically between the two slabs.

35.4.3 Closure Strips, Joints, and Favorable Pour Sequencing

A closure strip, also referred to as a *pour strip*, is a temporary separation of approximately 30 to 36 in. between two regions of slab that will be constructed and post-tensioned separately. Each region is allowed to independently undergo shortening. After a period of typically 30 to 60 days, the gap between the two post-tensioned slab regions (i.e., the closure strip) is closed by placing and consolidating nonshrink concrete. The reinforcement that extends from the concrete slab on each side into the closure strip provides the continuity of the slab over the strip.

The width of a closure strip is determined by the net distance required to position a stressing jack between the two sides of the strip and conclude the stressing operation. The reinforcement across the closure strip is designed on the basis of actions (moments and shears) occurring at the location of the strip when the entire slab is combined in a continuum. Between two adjacent supports, the preferred location of a closure strip is, for regular conditions, at a quarter span where the moments are typically small. Other considerations, however, may dictate the location of a closure strip. The position of the closure strip in relation to the entire slab is discussed at the end of this section. For corrosion protection, it is emphasized that, as a good practice, the stressing ends of the tendons terminating in the closure strip should be cut, sealed, and grouted in the same manner as at the free edges.

The time necessary to keep a closure strip open is determined by the extent of shortening deemed necessary before the two slab regions are tied together. Some engineers specializing in the design of post-tensioned slabs use an empirical value of 0.25 in. as the hypothetical displacement that can be accommodated in a post-tensioned member without apparent impairment of its serviceability. On this premise, a closure concrete should be placed when the calculated balance of shortening on each side of the closure strip is 0.25 in. or less. The shortenings are calculated using standard procedures in which concrete is assumed to be free to move. Obviously, when the closure strip has been poured and the two slab regions have been tied together, the balance of computed shortening referred to cannot take place. This empirical procedure is backed by the satisfactory performance of closure strips in place. It generally leads to closure-strip concreting between 14 to 120 days.

Construction joints are joints at predetermined locations in the slab between two concrete placements. The joints provide a planned temporary break between two slab regions for the purpose of crack control and construction operations. They are also used to subdivide a larger slab area into manageable sizes

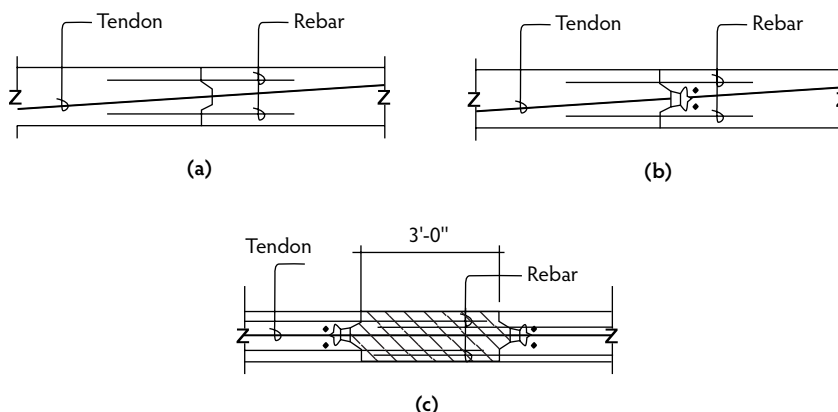

FIGURE 35.13 Details of slab joints: (a) construction joint with no stressing; (b) construction joint with intermediate stressing; (c) closure strip.

from a construction point of view. A construction joint as shown in Figure 35.13 differs from a cold joint in that (1) its location is determined by design as opposed to the location at which a concrete batch is finished, and (2) a gap of 3 to 7 days commonly occurs between the placement of first pour and the second pour; this time gap is applicable to joints that are designed for crack control. Construction joints may or may not have intermediate stressing. Intermediate stressing of tendons is carried out for long tendons where friction losses are appreciable.

From the performance experience of post-tensioned slabs, the following guidelines for the provision of closure strips or structural separations may be considered:

- If the slab length is less than 250 ft, no closure strip or structural separations are necessary, unless the supporting walls are unfavorably placed.
- If the slab length is longer than 250 ft but less than 375 ft, provide one centrally located closure strip.
- If the slab length is longer than 375 ft, provide a structural separation.

35.4.4 Released Connections

Released connections are effective means of crack mitigation when a favorable layout of supporting structural elements or provision of construction separations and closure strips cannot be fully implemented. Released connections are those in which a joint is detailed and constructed so as to permit a limited movement of the slab relative to its support. Released connections may be used in conjunction with closure strips and structural joints. Released connections with successful results are now common practice for post-tensioned slab construction in California. Released connections are grouped into wall/slab release, slab joints, and wall joints.

35.4.4.1 Wall/Slab Release

Figure 35.14 shows several types of commonly used wall/slab connections. To facilitate slippage, a slip material is normally provided at the interface of wall and slab. For simplicity in presentation, the connections shown are for the end walls and a terminating roof slab, but they are equally applicable, with appropriate modifications, to interior walls and intermediate slabs. The connection type with no ties between the slab and its supporting wall (Figure 35.14a) is the most effective release joint, but its application is restricted by the fact that, in many cases, walls must be designed to transfer shear forces, in addition to gravity loading, at their interface with the slabs. Moreover, the stability of the walls due to lateral loads may become a governing consideration. Such releases, where possible, are employed at the corners of the slab areas. It is recommended that the maximum length of a no-tie release be limited

FIGURE 35.14 Typical details of different wall-slab connection types.

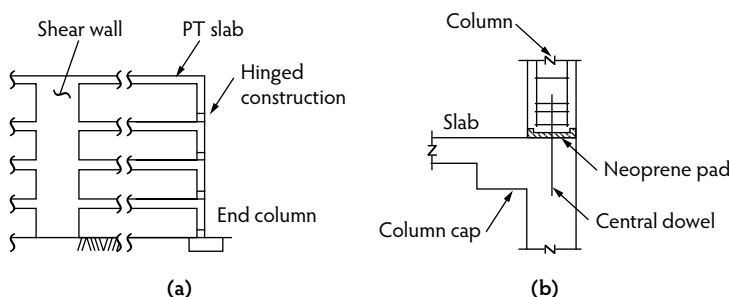

FIGURE 35.15 Hinged construction at base of end columns: (a) elevation; (b) detail of hinge construction.

to the height of the respective wall. A permanent release with a dowel encased in a compressible material is shown in Figure 35.14b. The dowel is provided to impede catastrophic movements of the wall, as in the event of an earthquake. This permanent release detail is used more frequently than the no-tie connection; however, it is more costly and requires greater care during construction. A temporary release as shown in Figure 35.14d is one where the slab is initially constructed released from the wall. After the shortening of the slab has taken place, to the extent that the balance is considered acceptable, the joint is fixed by grouting the pockets.

35.4.4.2 Slab–Column Release

Columns may be designed to withstand the anticipated forces conducive to lateral displacements between their ends without signs of distress or may be released to accommodate relative displacements of slab to column at the joints. The latter option, where applicable, leads to superior slab performance. Several items must be reviewed in arriving at a satisfactory solution. Maximum displacements are typically at the end columns, as shown in Figure 35.15. A detail providing rotational release at the base of the column, as shown in the same figure, may prove adequate. Where columns are excessively bulky, as may be required for architectural reasons, it becomes necessary to provide a detail that accommodates displacements in addition to rotation.

35.4.4.3 Wall Joints

Wall joints are vertical separations between adjacent walls that enable the walls to accommodate displacements of slabs or beams supported by walls. Wall joints are very effective in mitigating cracks in slabs or beams, as well as cracks in the supporting walls themselves. Figure 35.16 shows the plan of a rectangular slab resting on perimeter walls and interior columns. For clarity, the columns are not shown. The wall joints (WJ) provided at the corners of the slab extend through the entire height of the walls. They allow the end wall to move toward the center of the slab without being impeded by the longitudinal

FIGURE 35.16 Wall joints: (a) plan showing wall joints (WJ) and closure strip above; (b) plan showing arrangement of various wall-slab connections.

FIGURE 35.17 Elevation of corner wall showing wall joint.

FIGURE 35.18 Crack-mitigating rebar next to shear walls: (a) interior shear wall; (b) exterior shear wall.

walls. Such wall joints perform best when accompanied by a slip joint between the slab and cross walls as shown in Figure 35.17. The detail shows joints with no ties at the corners which allows the wall shown on left to follow the movement of the slab to the right without interference from the cross wall shown in elevation. The size of the gap is estimated to be 0.75 in. per 100 ft of slab movement accommodated by the wall. Wall joints need not in all cases extend through the entire height of a wall down to the lower level.

35.4.5 Addition or Improved Layout of Mild Reinforcement

In addition to the well-planned layout of shear walls and supporting structures and provision of releases, it is necessary to place additional mild reinforcement at locations of potential distress to mitigate crack formation. Figure 35.18 and Figure 35.19 illustrate examples of typical cases. Figure 35.18 shows reinforcement added next to nonreleased exterior walls. Due to design shear-transfer requirements between a slab and its supporting wall, it might not always be feasible to provide sufficient release details to prevent all cracks. The reinforcement shown in Figure 35.18 has been found to be highly effective for such conditions. The steel is placed parallel to the wall over a width equal to approximately 10 ft normal to the wall. The steel area is determined as 0.0015 times the cross-sectional area of the slab over one third of the transverse span. The bars are spaced alternately at the top and bottom at approximately 1.5 times the slab thickness. Note that this is not a code requirement but rather a practice found to yield satisfactory results for the elimination of potential restraint cracks.

FIGURE 35.19 Reinforcement at slab corners.

FIGURE 35.20 Tendon arrangement to compensate restraining effects of transverse walls.

FIGURE 35.21 Tendon arrangement for mitigating cracks in central spans.

35.4.6 Addition or Improved Layout of Tendons

Figure 35.20 and Figure 35.21 show two conditions where wall restraints can lead to significant losses of precompression in the central region of the slab and consequently lead to formation of cracks. In addition to other measures, such as the releases described in the preceding sections, it is helpful to lay out the tendons so as to deposit additional compression in regions where losses are expected to be highest. Dead ending and overlapping of tendons as illustrated in Figure 35.20 and Figure 35.21 can serve this purpose. The detailing of strand layout around discontinuities and openings is also of importance. Figure 35.22 illustrates two arrangements for tendon layout at an interior opening. The detail on the right shows a common practice where the sides of the opening are pulled apart. Cracks at the corners of such openings are not uncommon. The detail on the left demonstrates an alternative tendon layout, where the opening is provided with an additional precompression ring to counteract crack-precipitating stresses at the corners.

35.5 Crack Evaluation Summary

From a study of crack formation in post-tensioned structures, a number of general conclusions have been formulated, as follows:

FIGURE 35.22 Arrangement of tendons at an interior opening.

- Shortening cracks (cracks due to constraint against free movement of the slab) are common in post-tensioned slabs supported on walls and stiff columns.
- Shortening cracks can be reduced significantly through crack-mitigation measures; the principal crack reduction procedures are:

Planning for layout of constraints

Structural separations

Closure strips, joints, and favorable pour sequencing

Released connections

Addition or improved layout of mild reinforcement

Addition or improved layout of tendons

With regard to implementation of crack-mitigation procedures, the following guidelines are suggested: (1) For small and simple slab geometries (10,000 ft² or less) supported on regular-size columns, design the slab to withstand the forces generated by shortening; it is not generally cost effective to implement crack-mitigation measures. (2) For slabs with substantial restraint, it is necessary to implement crack-mitigation measures.

- Most shortening cracks are not structurally significant. The most common cause of shortening of shortening cracks is the exposure of reinforcement and post-tensioning to corrosive elements; aesthetics and leakage are the next most common considerations.
- For slabs with significant support restraints, such as perimeter walls, it is often necessary to conduct a one-time maintenance routine to repair shortening cracks. In such cases, notes should be added to the structural drawings indicating the following:

Shortening cracks are likely to occur.

Shortening cracks do not normally impair the structural integrity of slabs.

Slabs should have a one-time crack maintenance operation, which consists of (1) inspecting and evaluating slabs and supporting members 2 years after construction, (2) determining cracks to be repaired, and (3) repairing cracks.

35.6 Maintenance

35.6.1 Structural and Preventative Maintenance

The most significant maintenance requirements in concrete structures are those associated with buildings having supported deck slabs and underlying structural frame members exposed to the environment such as open parking structures. Concrete is one of the most durable and low-maintenance construction materials available today; however, these attributes have led some building owners to believe that concrete structures are maintenance free. It is important for the engineer to point out to the contractor and owner that even concrete structures require continuous maintenance to retain the strength and serviceability of

the structure. One effective way to accomplish this is to add appropriate maintenance requirements in the form of general notes on the construction documents. An example of such a reference is provided below:

Maintenance:

The entire concrete frame, including elevated slabs, beams, walls, columns, slab-on-ground, and exterior concrete façade, requires continuous maintenance to remain serviceable and safe. Details of the maintenance program applicable to this project must be prepared by the owner (or designated consultant) and submitted to the facility maintenance department for execution. Failure to do so may render the structure nonserviceable or unsafe during the useful lifecycle of the structure. As a guide, the following references may be consulted as minimum requirements: Chapter 9 in *Parking Structures*, by Anthony P. Chrest and Sam Bhuyan (Routledge, 1989); *Guide for Structural Maintenance of Parking Structures* (ACI 362.2R); and *Design, Construction, and Maintenance of Cast-in-Place Post-Tensioned Concrete Parking Structures* (Post-Tensioning Institute, 2001).

When selecting a maintenance program it is necessary to address the strength and serviceability of the structural members. Structural maintenance requirements are those actions necessary to test the integrity of the material components of the structure and member configuration. Preventative maintenance requirements are those actions that improve or enhance serviceability (e.g., waterproofing, corrosion). See Table 35.2 for a summary of maintenance tasks.

TABLE 35.2 Parking Facility Structural Maintenance: Tasks and Frequencies

Task	Recommended	Minimum	Procedure
Sweep	W	M	Power sweep, vacuum, or hand sweep.
Wash down decks ^a	S	A	Hose down decks, ramps, and curbs.
Touch-up deck sealer ^b	AR	S	Reapply sealer as necessary.
Check for and evaluate cracks	AR	A	Check for leaks. Rout cracks and fill with sealant.
Check joint sealants	AR	S	Determine if cracks are structural or nonstructural.
Check isolation joint seals	AR	S	Look for leaks, adhesive or cohesive failure, tears, and adjacent concrete failures. Repair on spot basis as required.
Check traffic-bearing membrane ^b	AR	S	Review for leaks, nosing or gland damage, tears, and punctures. Repair as required.
Repaint structural steel or exposed metal	AR	A	Review wear, tear, blisters, delamination, cracks, and leaks. Repair on spot basis as required.
Check for deck surface deterioration	AR	A	Inspect for chips, peeling, and rust. Repaint on spot basis. Use special coatings, if required.
Check for water leaks	AR	S	Review for cracks, joint edge spalls, scaling, and delaminations. Repair on spot basis, as required.
Check for leakage	S	—	Consult with an engineer if deterioration is extensive.
Inspect deck drain system	M	S	Identify location and source.
Check for ponded areas	AR	A	Take corrective action as required.
Evaluate condition of previous repairs	AR	A	Drains: Remove debris and clean out drain.
Have a condition survey performed	A	AR	Drain lines: check for leaks and drainage.
			If ponding is evident, consider installing an area drain or reestablishing drainage lines.
			Evaluate condition of previous repairs; note any additional maintenance required.
			Survey should be performed periodically by a qualified structural engineer as required by conditions.

^a As weather permits.

^b This element should be maintained under warranty or service contract. Check with the manufacturer or authorized representative for terms of coverage.

Frequency: W, weekly; A = annually; AR = as required, M = monthly; S, semiannually. For items marked “As Required,” select a maintenance frequency appropriate for the particular element. Perform local repairs or replacement as needed. Special attention should be paid to areas exposed to direct sunlight or high wear, such as entries and exits, ramps, and turning aisles. Review with an engineer if uncertain about structural effects.

35.6.1.1 Concrete Slabs

The most common cause of deterioration of deck slabs and surfaces is the penetration of water and deicing chemicals into and through the slab. Preventive-maintenance measures, such as applying a protective sealer, elastomeric coating, or sealants, are most effective when applied to a new slab. On existing structures with chloride-ion contamination, the ability of a coating or sealer to suppress corrosion will depend on its ability to reduce the moisture content of the concrete. Coatings are normally more effective than sealers in reducing moisture absorption. They will not stop the corrosion completely, however, unless the chloride-ion contamination of the underlying substrate is below the corrosion threshold.

To reduce the impact of progressive deterioration and maintain serviceability, spall delaminations in the deck slab should be evaluated and patched in an appropriate manner. Temporary repairs may sometimes be required because of the time or weather constraints. Temporary repairs can be done with appropriate repair materials until long-term repairs are possible. Tar and asphaltic materials should not be used for temporary patches, however, as these will allow the migration of water and chloride ions into the concrete. Refer to ACI 546 for additional information for guidance on repair options.

Long-term repairs will require removal of all of the deteriorated concrete. Corroded reinforcement should be completely exposed, cleaned, and covered with a corrosion-inhibiting coating. Reinforcing that has lost more than 20 or 25% of its cross-sectional area may require replacement. The repair area should then be patched with an appropriate patching material. If a Portland cement-based material is used for the patches, proper curing is essential to ensure durability.

Cracking is a key cause of more serious deterioration problems in deck slabs. Fine hairline cracks can often be sealed with a low-viscosity silane sealer. Larger cracks should be routed out and sealed with a flexible, traffic-grade sealant (the rout-and-seal method). For numerous, closely spaced cracks, a traffic-bearing membrane should be installed over the area. Before the membrane is installed, the cracks should be routed and sealed or otherwise detailed in accordance with recommendations from the membrane manufacturer. If there are concerns that the cracks compromise the integrity of the structure, they should be evaluated by the engineer of record or a professional engineer with experience in structural restoration.

Ponding can also lead to significant deterioration and leakage problems. Poor finishing of the concrete can result in small areas of local ponding. Large areas of standing water are usually an indication that wither slopes to drains are not adequate or the drains do not have enough capacity. Ponding can usually be corrected by installing supplemental drains. Resurfacing to reestablish proper drainage lines may be required if the problem is widespread. Adding supplemental drains is typically the most economical approach to correct poor drainage situations, however. Refer to ACI 515.1R (ACI Committee 515, 1985) for additional information.

35.6.1.2 Beams, Columns, and Facades

Beam and column deterioration can adversely affect the structural integrity and load-carrying capacity of the structure. Deterioration of these underlying members is primarily caused by water leakage through failed joints and deck slab cracks. The vertical surfaces of columns and exterior concrete facades (spandrel railing) are also susceptible to damage from ponding water and salt splashing from moving vehicles. Beams and columns adjacent to and below expansion joints are especially susceptible to deterioration. Water leakage can contribute to freeze-thaw deterioration, corrosion of reinforcement and connections, rust staining, and leaching. Degradation can be minimized by proper maintenance of the joint sealant systems and application of a sealer or elastomeric membrane to the column bases and spandrel railing. These members are also vulnerable to user damage such as vehicle impact. They should be examined periodically for cracking and spalling. Runoff water that collects along or adjacent to interior face of exterior spandrel walls and columns can contribute to corrosion of exposed steel embedments and exposed reinforcement of these elements. This can lead to unsightly rust staining and, in extreme cases, safety concerns about the load-carrying capacity of the embedded steel. If significant ponding is present, it may be necessary to install a curb or supplemental drain to slope the concrete and move water away from the affected areas.

35.6.1.3 Stair and Elevator Towers

Leaks often occur at the joints between deck slabs and stair and elevator towers. These leaks are typically due to poor drainage around the towers. If not addressed, these leaks can cause severe deterioration of underlying elements such as metal doors, light fixtures and electrical conduits, metal stairs, exposed structural steel members, and precast connections. Drainage can be improved by providing curbs to divert the water. Frequent inspection and immediate repair of damaged isolation joints between the tower and the deck surface will also reduce the potential for deterioration. Masonry walls should typically be sealed. If a masonry wall is exposed to the weather, however, nonbreathing paints should not be used on both sides as this will tend to trap water and cause the paint to peel. Stair and elevator wall cracking should be repaired, as appropriate, to minimize moisture penetration.

35.6.1.4 Exposed Metals

An exposed concrete frame such as a parking structure may have exposed metals in the form of stairs, pedestrian railings, vehicular guardrails, precast connections, columns, or beams. Exposed metals should be visually monitored on a regular basis. Premature deterioration of metal components can be the result of atmospheric exposure, neglect, or chemical reactions between metals. Galvanic processes between two dissimilar materials such as aluminum and mild steel at a connection may cause especially severe corrosion. Treatment of metals with a proper surface preparation and appropriate paint or anticorrosion coatings will help minimize corrosion and resultant problems. Metal pan stairs with concrete infill are particularly susceptible to corrosion-related deterioration. They are not recommended in areas that use deicing salts.

35.6.2 Operational and Aesthetics Maintenance

Operational maintenance involves the regular inspection, repair, and maintenance required to keep the structure functional for its intended users. It includes housekeeping tasks such as routine cleaning, sweeping and wash-downs, snowplowing, and ice control.

35.6.2.1 Housekeeping Requirements

Routine cleaning is one of the most important aspects of good housekeeping. A clean environment makes the concrete structure more pleasant, reduces required maintenance, and extends service life. Sweeping, for example, should be done at least monthly and can be done with hand brooms, mechanized sweepers, or vacuums designed for use in parking structures. All dirt and debris should be removed from the facility. Special attention should be paid to keeping dirt and debris out of drain basins, pipes, expansion joints, and other openings. Grease buildups should be removed regularly using appropriate degreasers. In freezing climates, road salts will accumulate over the winter months. They should be removed each spring by flushing the surface with large volumes of water at low to moderate pressure. A second wash-down is recommended in the fall to remove surface debris and contaminants. Parking structures should be equipped so a 1.5-in.-diameter hose can be used to wash the deck. Areas that tend to get a higher buildup of salt such as entrances and exits and flat or ponded areas should be washed more frequently. Care should be taken not to damage joint sealants, expansion joints, or deck coating materials. Drains should be flushed carefully to avoid plugging the drainage system with sand, dirt, and debris.

35.6.2.2 Snow Removal and Ice Control

Snowplows can damage joint sealants, isolation joint seals, and concrete traffic-deck coatings. Columns, curbs, walls, and even the decks themselves can be damaged by snow removal activities. Care should be taken to use equipment that had been properly adapted to avoid direct contact with the structure. Rubber-tipped snowplow blades are one solution to this problem. All isolation joints should be marked and pointed out to the snowplow operator. Hand removal may be necessary in certain areas to avoid damage to the seals. Piling snow on the deck slab is not permissible. Packed snow can be heavy and may exceed the load capacity of the deck and contribute to cracking. Piles of snow may also create a reservoir of salt-

contaminated water that contributes to leakage and chloride buildup. Deicing chemicals are used to control ice buildup and reduce slipping and skidding hazards; however, most common chemical deicers can damage the concrete or reinforcing steel, and they should be used with caution. Calcium magnesium acetate (CMA) is considered to be less corrosive than common road salt or calcium chloride. Care should also be taken to ensure that any deicers used comply with local health and environmental codes.

35.6.2.3 Other Operational Maintenance

A parking structure has a number of operational systems. These include mechanical and electrical systems, lighting, elevators, signage, parking control equipment, security systems, graphics, and striping. Although they typically do not affect structural performance, it is sometimes cost effective to coordinate the maintenance or updating of these systems with structural maintenance. Refer to the *Parking Garage Maintenance Manual* (Parking Consultants Council, 2004) for additional information.

35.6.2.4 Aesthetics-Related Maintenance

Maintenance must address the aesthetic as well as structural and operational aspects features of a concrete structure. Aesthetics includes items such as landscaping, painting, and general appearance. Patrons appreciate a clean facility and are more inclined to treat it properly, which can ultimately reduce repair costs.

35.6.3 Checklist for Structural Inspection

A regular visual inspection of the structural and waterproofing components of the parking structure is an essential element of a preventive maintenance program. The inspection should be conducted in conjunction with a wash-down of the structure so any active leakage can be noted. The structure should be inspected systematically and the nature, location, and severity of any observed problems recorded. It is helpful to have a notebook-sized plan of each floor to use as a base sheet for taking notes during the inspection. In addition, it is helpful to develop a system of marks for use in representing various conditions while taking field notes. A digital camera or videocamera can be of great assistance in documenting developing problems. While most problems can be observed by a layperson familiar with the structure, an inspection should be performed by a qualified engineer every few years or when new or significant changes in deterioration are observed. Visual inspection of the parking structure should include the following items. (Any “Yes” answers should be followed up with action to remedy the situation.)

Deck

- Yes ☐ No ☐ Are there any cracks?
- Yes ☐ No ☐ If so, do they leak?
- Yes ☐ No ☐ Is the surface sound (or are there areas where surface scaling is present)?
- Yes ☐ No ☐ Is there any evidence of corrosion of reinforcing steel or surface spalling?
- Yes ☐ No ☐ Is there any evidence of corrosion of exposed metals?
- Yes ☐ No ☐ Is there any evidence of concrete delamination?
- Yes ☐ No ☐ Is any steel reinforcing exposed?
- Yes ☐ No ☐ Are there any signs of leakage? (Describe conditions and note location.)
- Yes ☐ No ☐ If there is a traffic-bearing membrane, are there any tears, cracks, or loss of adhesion?
- Yes ☐ No ☐ Are there low spots where ponding occurs?
- Yes ☐ No ☐ Has the concrete been tested for chloride ion content? (When was it last monitored? Are there records available?)
- _____ When was the deck last sealed?

Beams and Columns

- Yes ☐ No ☐ Are there any cracks? (If so, are they vertical or horizontal; how long and wide?)
- Yes ☐ No ☐ Are there any signs of leakage? (Describe conditions and note location.)
- Yes ☐ No ☐ Is there any concrete spalling?
- Yes ☐ No ☐ Is any steel reinforcement exposed?

Stair and Elevator Towers

- Yes ☐ No ☐ Are there any signs of a leaking roof?
 Yes ☐ No ☐ Are there any cracks in the exterior finish?
 Yes ☐ No ☐ Is any other corrective action required?

Isolation Joints

- Yes ☐ No ☐ Are there any leaks through isolation joint seals?
 Yes ☐ No ☐ If so, are they related to seal failure or failure of the adjacent concrete?
 Yes ☐ No ☐ Could the cause of these leaks be snowplows?
 _____ What type of isolation joint seal is it? Who is the manufacturer?
 Yes ☐ No ☐ Is there any isolation joint warranty in force? (Consult with the manufacturer for repair recommendations.)

Joint Sealants

- Yes ☐ No ☐ Are there any signs of leakage, loss of elastic properties, separation from adjacent substrates, or cohesive failure of the sealant?
 Yes ☐ No ☐ Are there any failures of the concrete behind the sealant (edge spalls)?

Exposed Steel

- Yes ☐ No ☐ Is there any exposed steel (structural beams, handrails, door frames, barrier cable, exposed structural connections)?
 Yes ☐ No ☐ Is rust visible on any exposed steel?
 Yes ☐ No ☐ If so, is it surface rust?
 Yes ☐ No ☐ Is there significant loss of section due to the rust?
 Yes ☐ No ☐ Is repainting required?

Drains

- Yes ☐ No ☐ Are the drains functioning properly? (When were they last cleaned out?)
 Yes ☐ No ☐ Are the drains properly located so they receive the runoff as intended?

Previous Repairs

- Yes ☐ No ☐ Are previous repairs performing satisfactorily?

Most structural systems constructed today are made from reinforced, prestressed, or composite concrete having a wide range of characteristics and strengths. Structural concrete, whether normal weight or lightweight, is designed to have a compressive strength in excess of 3000 psi (20 MPa) in concrete structures. When the strength exceeds 6000 psi (42 MPa) such structures are defined today as high-strength concrete structures. Concrete mixtures designed to produce 6000 to 12,000 psi in compressive strength are easily obtainable today when silica fume or other pozzolans replace a portion of the cement content, resulting in lower water/cement (w/c) and water/cementitious materials (w/cm) ratios. Concretes

* Distinguished Professor, Civil Engineering, Rutgers University, The State University of New Jersey, Piscataway, New Jersey, and ACI honorary member; expert in concrete structures, materials, and forensic engineering.

having cylinder compressive strengths of about 20,000 psi (140 MPa) have been used in several buildings in the United States. These high-strength characteristics merit qualifying such concrete as super-high-strength concrete at this time.

36.1 Material Characteristics

36.1.1 Modulus of Concrete

The ACI 318 Code (ACI Committee 318, 2008; Nawy, 2002, 2008) stipulates that the concrete modulus of elasticity (E_c) should be evaluated from:

$$E_c \text{ (psi)} = 33w^{1.5}\sqrt{f'_c} \quad (36.1a)$$

$$E_c \text{ (MPa)} = 0.043w^{1.5}\sqrt{f'_c} \quad (36.1b)$$

The expressions in Equation 36.1 are applicable to strengths up to 6000 psi (42 MPa). Available research to date for concrete compressive strength up to 12,000 psi (83 MPa) gives the following expressions (ACI Committee 435, 1995; Nawy, 2002, 2008):

$$E_c \text{ (psi)} = \left(40,000\sqrt{f'_c} + 10^6\right)\left(\frac{w_c}{145}\right)^{1.5} \quad (36.2a)$$

$$E_c \text{ (MPa)} = \left(3.32\sqrt{f'_c} + 6895\right)\left(\frac{w_c}{2320}\right)^{1.5} \quad (36.2b)$$

In Equation 36.1a and Equation 36.2a, f'_c is in units of pounds per square inch, and w_c ranges between 145 pcf for normal-density concrete and 100 pcf for structural lightweight concrete; f'_c in Equation 36.1b and Equation 36.2b is in units of megapascals and w_c ranges between 2400 kg/m³ for normal-density concrete and 1765 kg/m³ for lightweight concrete. The modulus of rupture of concrete can be taken as:

$$f_r \text{ (psi)} = 7.5\lambda\sqrt{f'_c} \quad (36.3a)$$

$$f_y \text{ (MPa)} = 0.632\lambda\sqrt{f'_c} \quad (36.3b)$$

where:

λ = 1.0 for normal-density stone aggregate concrete.

λ = 0.85 for sand lightweight concrete.

λ = 0.75 for all lightweight concrete.

36.1.2 Creep of Concrete

Concrete creeps under sustained loading due to transverse flow of the material. The creep coefficient as a function of time can be calculated from the following expression (ACI Committee 435, 1995; Nawy, 2002, 2008):

$$C_t = \left(\frac{t^{0.6}}{10 + t^{0.6}}\right)C_u \quad (36.4)$$

where time t is in days and C_u , the ultimate creep factor, is 2.35. The short-term deflection is multiplied by C_t to get the long-term deflection, which is added to the short-term (instantaneous) deflection value to obtain the total deflection.

FIGURE 36.1 Long-term deflection multipliers. (From ACI Committee 318, *Building Code Requirements for Structural Concrete*, ACI 318-08; *Commentary*. ACI 318R, American Concrete Institute, Farmington Hills, MI, 2008.)

36.1.3 Shrinkage of Concrete

Concrete shrinks as the absorbed water evaporates and the chemical reaction of cement gel proceeds. For moist-cured concrete, the shrinkage strain that occurs at any time t in days 7 days after placing the concrete can be evaluated from (ACI Committee 435, 1995):

$$(\epsilon_{SH})_t = \left(\frac{t}{35+t} \right) (\epsilon_{SH})_u \quad (36.5a)$$

For steam-cured concrete, the shrinkage strain at any time t (in days) 1 to 3 days after placement of the concrete is:

$$(\epsilon_{SH})_t = \left(\frac{t}{55+t} \right) (\epsilon_{SH})_u \quad (36.5b)$$

where maximum $(\epsilon_{SH})_u$ can be taken as 780×10^{-6} in./in. (mm/mm).

Shrinkage and creep due to sustained load can also be evaluated from the ACI expression (ACI Committee 318, 2008):

$$\lambda = \left(\frac{\xi}{1+50\rho'} \right) \quad (36.5c)$$

and Figure 36.1 for the factor ξ that ranges from a value of 2.0 for 5 years or more to 1.0 for 3 months of sustained loading; $\rho' = \text{compression steel percentage} = A_s'/bd$.

36.1.4 Control of Deflection

Serviceability is a major factor in designing structures to sustain acceptable long-term behavior. Serviceability is controlled by limiting deflection and cracking in the members (ACI Committee 435, 1995). For deflection computation and control, the effective moment of inertia of a cracked section can be evaluated from the Branson equation:

$$I_e = \left(\frac{M_{cr}}{M_a} \right) I_g + \left[1 - \left(\frac{M_{cr}}{M_a} \right)^3 \right] I_{cr} \leq I_g \quad (36.6)$$

where, for reinforced-concrete beams:

- M_{cr} = cracking moment due to total load = $(f_r I_g)/y_t$.
 y_t = distance from the neutral axis to the extreme tension fibers.
 M_a = maximum service load moment at the section under consideration.
 I_g = gross moment of inertia.

In the case of prestressed concrete,

$$\left(\frac{M_{cr}}{M_a} \right) = \frac{f_{te} - f_r}{f_L} \quad (36.7)$$

where:

- M_{cr} = moment due to that portion of live load moment M_a that causes cracking.
 M_a = maximum service load (unfactored) live load moment.
 f_{te} = total calculated stress in the member.
 f_L = calculated stress due to live load.

For long-term deflection, Figure 36.1 gives the required multipliers as a function of time.

36.1.5 Control of Cracking in Beams

Control of cracking in beams and one-way slabs can be made using the expression (ACI Committee 224, 2001):

$$w_{\max} \text{ (in.)} = 0.076 \beta f_s \sqrt[3]{d_c A} \times 10^{-3} \quad (36.8a)$$

where:

- w_{\max} = crack width (in.) (25.4 mm).
 β = $(h - c)/(d - c)$.
 d_c = thickness of cover to the first layer of bars (in.).
 f_s = maximum stress in reinforcement at service load = $0.60 f_y$ (kips/in.²).
 A = area of concrete in tension divided by number of bars (in.²) = bt/γ , where γ is the number of bars at the tension side.

36.1.6 ACI 318 Code Provisions for Control of Flexural Cracking

From the author's work and briefly reported in Nawy (2002, 2005), the spacing of the reinforcement is a major parameter in limiting the crack width. As the spacing is decreased through the use of larger numbers of bars, the area of the concrete envelopes surrounding the reinforcement increases. This leads to a larger number of narrower cracks. As the crack width becomes narrow enough within the values given in Table 36.1, corrosion effects on the reinforcement are considerably reduced. The current ACI provisions on crack control deal with this problem by limiting reinforcement spacing in reinforced-concrete beams and one-way slabs to the values obtained from the following expression for maximum allowable bar spacing:

$$s = 15 \left(40,000 / f_s \right) - 2.5c_c \quad (36.8b)$$

but not greater than $12(40,000/f_s)$, where:

- f_s = calculated stress in reinforcement at service load = unfactored moment divided by the steel area and the internal arm moment; f_s is taken as $2/3 f_y$ (psi).
 c_c = clear cover from the nearest surface in tension to the flexural tension reinforcement (in.).
 s = center-to-center spacing of flexural tension reinforcement (in.) closest to the tension face of the section.

TABLE 36.1 Tolerable Crack Widths

Exposure Condition	Tolerable Crack Width	
	in.	mm
Dry air or protective membrane	0.016	0.41
Humidity, moist air or soil	0.012	0.30
Deicing chemicals	0.007	0.18
Seawater and seawater spray; wetting and drying	0.006	0.15
Water-retaining structures (excluding non-pressure pipes)	0.004	0.10

From these provisions, the maximum spacing for 60,000-psi (414-MPa) reinforcement = $12[36/(0.6 \times 60)] = 12$ in. (305 mm). The maximum spacing of 12 in. conforms with tests conducted by the author on more than 100 two-way action slabs; hence, this limitation on the distribution of flexural reinforcement in one-way slabs and wide-web reinforced-concrete beams is appropriate. In beams of normal web width in normal buildings, however, these provisions might not be as workable as controlling the crack width through the use of crack-width expressions to control the crack width within tolerable limits.

The SI expression for the value of reinforcement spacing in Equation 36.8b and f_s (MPa) is:

$$s \text{ (mm)} = 380 \left(280/f_s \right) - 2.5c_c \quad (36.8c)$$

but not to exceed $300(252/f_s)$. For the usual case of beams with grade-420 reinforcement and 50-mm clear cover to the main reinforcement and with $f_s = 252$ MPa, the maximum bar spacing is 300 mm.

It should be stressed that these provisions are applicable to reinforced-concrete beams and one-way slabs in structures subject to normal environmental conditions. For other types of structures subject to aggressive environment such as sanitary structures, refer to ACI Committee 350 (2006), Nawy (2002, 2008), and Table 36.1 for values of tolerable crack widths in reinforced-concrete structures.

36.2 Structural Design Considerations

High-strength concretes have certain characteristics and engineering properties that differ from those of lower strength concretes (ACI Committee 363, 1992). These differences seem to have larger effects as the strength increases beyond the current 6000-psi (42-MPa) plateau for normal-strength concrete. High-strength concretes are shown to be essentially linearly elastic up to failure, with a steeper declining portion of the stress–strain diagram. In comparison, the stress–strain diagram of lower strength concretes is more parabolic in nature, as seen in Figure 36.2. The stress–strain relationship of the steel reinforcement in this diagram is not to scale in its ordinate value but is intended to show the relative strain following the usual assumption of strain compatibility between the concrete and the steel reinforcement up to yield.

36.2.1 Axially Loaded Columns

Current design practice adds the contribution of the steel and the concrete to calculate the ultimate state of failure in compression members. For lower strength concretes, when the concrete reaches the nonlinearity load level at a strain of 0.001 in./in., as seen in Figure 36.2, the steel is still in the elastic range, assuming a larger share of the applied load. But, as the strain level approaches 0.002 in./in., the slope of the concrete stress–strain diagram approaches zero, while the steel reaches its yield strain that will thereafter be idealized into a constant (horizontal) plateau. The strength of the column using the addition law would then be:

$$P_n = 0.85f'_cA_c + f_yA_s \quad (36.9)$$

where:

FIGURE 36.2 Concrete and steel stress–strain relationships. (From ACI Committee 363, *State-of-the-Art on High-Strength Concrete*, ACI 363R, American Concrete Institute, Farmington Hills, MI, 1992, pp. 1–55.)

f'_c = concrete cylinder compressive strength.

f_y = yield strength of the reinforcement.

A_c = gross area of the concrete section.

A_s = area of the reinforcement.

The factor 0.85 representing the adjustment in concrete strength between the cylinder test result and the actual concrete strength in the structural element has been shown by extensive testing to be sufficiently accurate for higher strength concretes (ACI Committee 363, 1992; Nawy, 2008).

Confining the concrete in compression members through the use of spirals or closely spaced ties increases its compressive capacity. The increase in concrete strength due to the confining effect of the spirals can be represented by the following expression:

$$f'_2 = \frac{1}{4} [\bar{f}_c - f''_c] \quad (36.10a)$$

where:

f'_2 = concrete confining stress due to the spiral.

\bar{f}_c = compressive strength of the confined concrete.

f''_c = compressive strength of the unconfined column concrete.

The hoop tension force in the circular spiral is:

$$2A_{sp}f_y = f'_2D'_s$$

FIGURE 36.3 Stress–strain diagrams of 4 × 6-in. normal weight, spirally confined compression prisms. (From Martinez, S. et al., *ACI Struct. J.*, 81(5), 431–442, 1984.)

or

$$f'_2 = \frac{2A_{sp}f_y}{D'_s} \quad (36.10b)$$

where:

A_{sp} = cross-sectional area of the spiral.

D'_s = diameter of concrete core.

s = spiral pitch.

Equation 36.10 can be improved (ACI Committee 363, 1992; Nawy, 2002), leading to the following form for normal weight concrete:

$$(\bar{f}_c - f'_c) = 4.0f'_2(1 - s/D'_s) \quad (36.11a)$$

and for lightweight concrete:

$$(\bar{f}_c - f'_c) = 1.8f'_2(1 - s/D'_s) \quad (36.11b)$$

Figure 36.3 gives the results of peak stress comparisons vs. axial strain for spirally reinforced members for low-, medium-, and high-strength concretes. For higher strength, it shows a lower strain at peak load and a steeper decline past the peak value; however, the strength gain in concrete due to confinement seems to be well predicted for high-strength concretes in Equation 36.11.

36.2.2 Beams and Slabs

36.2.2.1 The Compressive Block

The design of concrete structural elements is based on the compressive stress distribution across the depth of the member as determined by the stress–strain diagram of the material. For high-strength concretes, the difference in the shape of the stress–strain relationship discussed in connection with Figure 36.2 results in differences in the shape of the compressive stress block. Figure 36.4 shows possible compressive blocks for use in design. Figure 36.4c could more accurately represent the stress distribution

FIGURE 36.4 Concrete compressive stress block: (a) standard stress block; (b) equivalent rectangular block; and (c) modified trapezoidal block.

for higher strength concrete; however, the computed strength of beams and eccentrically loaded columns depends on the reinforcement ratio. In the ACI 318 Code provisions, which use the equivalent rectangular block, the nominal moment strength of a singly reinforced beam is calculated using the following expression:

$$M_n = A_s f_y d \left[1 - 0.59 \rho \frac{f_y}{f'_c} \right] \quad (36.12)$$

where the coefficient $0.59 = \beta_2 / \beta_1 \beta_3$. Although a detailed evaluation of the factors β_1 , β_2 , and β_3 indicates a significant difference in their separate values, depending on the concrete strength (ACI Committee 363, 1992), Figure 36.5 shows that these differences collectively balance each other and that the combined coefficient $\beta_2 / \beta_1 \beta_3$ is well represented by the 0.59 value. Consequently, for strengths up to 12,000 psi (42

FIGURE 36.5 Stress block parameter $\beta_2 / \beta_1 \beta_3$ vs. concrete compressive strength. (From ACI Committee 363, *State-of-the-Art on High-Strength Concrete*, ACI 363R, American Concrete Institute, Farmington Hills, MI, 1992, pp. 1–55.)

TABLE 36.2 Deflection Ductility Index for Singly Reinforced Beams

Beam	f'_c		ρ/ρ_b^a	Ductility Index ($\mu = \Delta_u/\Delta_y$)
	psi	MPa		
A1	3700	26	0.51	3.54

^a Ratio of tension reinforcement divided by reinforcement ratio producing balanced strain conditions.

Source: Data from Pastor, J.A. et al., *Behavior of High-Strength Concrete Beams*, Cornell University Report No. 84-3, Department of Structural Engineering, Cornell University, Ithaca, NY, 1984; Nawy, E.G., *Fundamentals of High-Performance Concrete*, 2nd ed., John Wiley & Sons, New York, 2002.

MPa), the current ACI 318 Code expressions requiring that beams be under-reinforced are equally applicable. For considerably higher strengths or for members combining compression and bending or for the over-reinforced members allowed in the codes, some differences in the value of $\beta_2/\beta_1\beta_3$ can be expected.

36.2.2.2 Compressive Limiting Strain

Although high-strength concrete achieves its peak value at a unit strain slightly higher than that of normal-strength concrete (Figure 36.2), the ultimate strain is lower for high-strength concrete unless confinement is provided. A limiting strain value allowed by the ACI 318 Code is 0.003 in./in. (mm/mm). Other codes allow a limiting strain for unconfined concrete of 0.0035 or 0.0038. The conservative ACI value of 0.003 seems to be adequate for high-strength concretes as well, although it is somewhat less conservative than that for lower strength concretes.

36.2.2.3 Confinement and Ductility

As higher strength concrete is more brittle, confinement becomes more important in order to increase its ductility. If μ is the deflection ductility index,

$$\mu = \frac{\Delta_u}{\Delta_y} \quad (36.13)$$

where:

Δ_u = beam deflection at failure load.

Δ_y = beam deflection at the load producing yield of the tensile reinforcement.

Table 36.2 shows the ductility index values of concretes in singly reinforced beams ranging in strength from 3700 to 9265 psi (25 to 64 MPa). The corresponding reduction in the ductility index ranges from 3.54 to 1.07. The addition of compressive reinforcement and confinement to geometrically similar beams seems to increase the ductility index for $f'_c = 8500$ up to a value of 5.61. Hence, the higher the concrete compressive strength, the more it becomes necessary to provide for confinement or the addition of compression steel (A_s') while using the same expression for nominal moment strength that is applicable to normal-strength concretes. It should be stated that cost would not be affected to any meaningful extent, as diagonal tension and torsion stirrups have to be used anyway, and in seismic regions closely spaced confining ties are a requirement. The maximum strain of confined concrete that can be utilized should not exceed 0.01 in./in. (mm/mm) in limit design.

36.2.2.4 Shear and Diagonal Tension

Design for shear in accordance with the ACI 318 Code is based on permitting the plain concrete in the web to assume part of the nominal shear V_n . If V_c is the shear strength resistance of the concrete, the web stirrups resist a shear force $V_s = V_n - V_c$. High-strength concrete develops a relatively brittle failure, as previously discussed, with the aggregate interlock decreasing with the increase in the compressive strength. Hence, the shear friction and diagonal tension failure capacity in beams might be unconservatively represented by the ACI 318 equations (Ahmed and Lau, 1987); however, the strength of the diagonal struts in the beam shear truss model is increased through the mobilization of more stirrups and the increased load capacity of the struts themselves. No research data are currently available to provide definitive guidelines on the minimum web steel that can prevent brittle failure. All work to date indicates no unsafe use of the current ACI 318 Code provisions for shear in the design of high-strength concrete members.

36.3 Strength Design of Reinforced-Concrete Members

36.3.1 Strain Limits Method for Analysis and Design

This approach is sometimes referred to as the *unified method*, as it is equally applicable to flexural analysis of prestressed concrete elements. The nominal flexural strength of a concrete member is reached when the net compressive strain in the extreme compression fibers reaches the ACI 318 Code strain limit of 0.003 in./in. It also stipulates that when the net tensile strain in the extreme tension steel (ϵ_t) is sufficiently large at a value equal or greater than 0.005 in./in., the behavior is fully ductile. The concrete beam section under this condition is characterized as being *tension controlled*, with ample warning of failure as denoted by excessive cracking and deflection.

If the net tensile strain at the extreme tension steel (ϵ_t) is small, such as in compression members, being equal or less than a *compression-controlled* strain limit, a brittle mode of failure is expected, with little warning of such an impending failure. Flexural members are usually tension controlled, and compression members are usually compression controlled; however, in some sections, such as those subjected to small axial loads but large bending moments, the net tensile strain (ϵ_t) in the extreme tensile reinforcement will have an intermediate or transitional value between the two strain limit states—namely, between the compression-controlled strain limit of $\epsilon_t = f_y/E_s = 60,000/29 \times 10^6 = 0.002$ in./in., and the tension-controlled strain limit $\epsilon_t = 0.005$ in./in. Figure 36.6 illustrates these three zones as well as the variation in the strength reduction factors applicable to the total range of behavior.

For the tension-controlled state, the strain limit $\epsilon_t = 0.005$ corresponds to the reinforcement ratio $\rho/\rho_b = 0.63$, where ρ_b is the reinforcement ratio for the balanced strain $\epsilon_t = 0.002$ in the extreme tensile reinforcement for 60-ksi steel. The net tensile strain $\epsilon_t = 0.005$ for a tension-controlled state is a single value that applies to all types of reinforcement, whether mild steel or prestressing steel. High reinforcement ratios that produce a net tensile strain less than 0.005 result in a ϕ -factor value lower than 0.90, resulting in less economical sections. Therefore, it is more efficient to add compression reinforcement if necessary or to deepen the section to make the strain in the extreme tension reinforcement (ϵ_t) ≥ 0.005 . Variation of the strain reduction factor ϕ as a function of strain for the range values of $\epsilon_t = 0.002$ and $\epsilon_t = 0.005$ can be linearly interpolated from the following expressions in terms of the limit strain ϵ_t :

Tied sections:

$$0.65 \leq \left[\phi = 0.65 + (\epsilon_t - 0.002) \left(\frac{250}{3} \right) \right] \leq 0.90 \quad (36.14a)$$

Spirally reinforced sections:

$$0.75 \leq \left[\phi = 0.75 + (\epsilon_t - 0.002) \left(\frac{150}{3} \right) \right] \leq 0.90 \quad (36.14b)$$

FIGURE 36.6 Strain limit zones and variation of strength reduction factor ϕ with the net tensile strain ϵ_t . (From ACI Committee 318, *Building Code Requirements for Structural Concrete*, ACI 318; *Commentary*. ACI 318R-08, American Concrete Institute, Farmington Hills, MI, 2008.)

Variation of ϕ as a function of the neutral axis depth ration c/d_t can be evaluated from the following two expressions for the limit ratios of c/d_t of 0.60 for the compression-controlled state and 0.375 for the tension-controlled state:

Tied sections:

$$0.65 \leq \left[\phi = 0.65 + 0.25 \left(\frac{1}{c/d_t} - \frac{5}{3} \right) \right] \leq 0.90 \quad (36.15a)$$

Spirally reinforced sections:

$$0.75 \leq \left[\phi = 0.75 + 0.15 \left(\frac{1}{c/d_t} - \frac{5}{3} \right) \right] \leq 0.90 \quad (36.15b)$$

36.3.2 Flexural Strength

36.3.2.1 Singly Reinforced Beams

Flexural strength is determined from the strain and stress distribution across the depth of the concrete section. Figure 36.7 shows the stress and strain distribution and forces. Taking moments of all the forces about tensile steel ($A_s' = 0$), a nominal moment strength:

$$M_n = A_s f_y \left(d - \frac{a}{2} \right) \quad (36.16)$$

$$M_n = bd^2 \omega (1 - 0.59\omega) \quad (36.17)$$

where ω = reinforcement index = $A_s/bd \times f_y/f_c'$.

FIGURE 36.7 Stress and strain distribution across beam depth: (a) beam cross-section; (b) strain across depth; (c) actual stress block; and (d) assumed equivalent stress block.

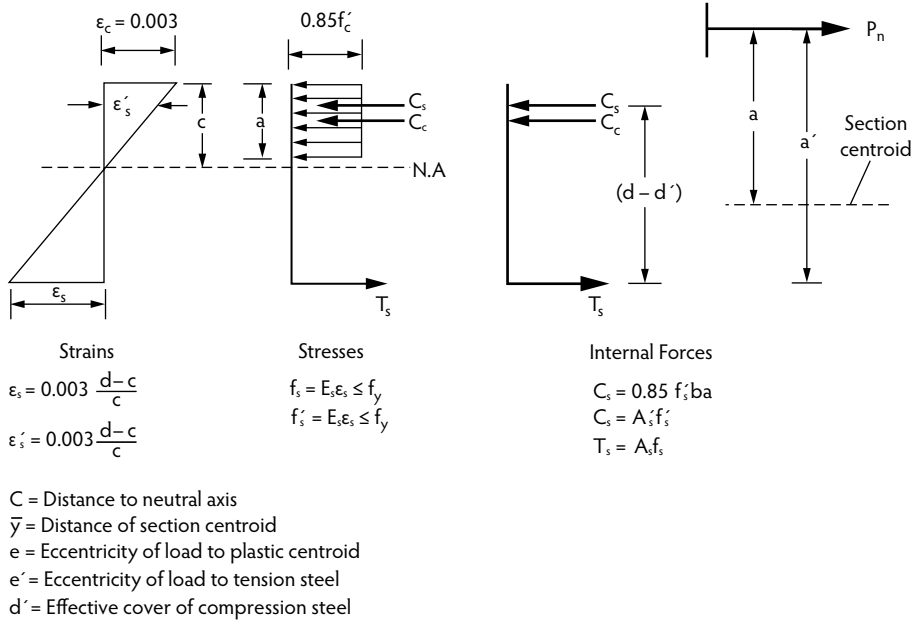

FIGURE 36.8 Stress-strain distribution across depth of compression member.

The balanced strain-state reinforcement ratio ρ_b for simultaneous yielding of the reinforcement at the tension side and crushing of the concrete at the compressions side can be obtained from the following expression:

$$\rho_b = 0.85\beta_1 \frac{f'_c}{f_y} \left(\frac{\epsilon_u}{\epsilon_u + 0.004} \right) \quad (36.18a)$$

where $\beta_1 = 0.85$ and reduces at the rate of 0.05 per 1000 psi in excess of 4000 psi, namely:

$$\beta_1 = 0.85 - 0.05 \left(\frac{f'_c - 1000}{1000} \right) \quad (36.18b)$$

with a minimum β_1 value of 0.65.

36.3.2.2 Doubly Reinforced Beams

For doubly reinforced sections that have compression steel that yielded:

$$M_n = (A_s - A'_s) f_y \left(d - \frac{a}{2} \right) + A'_s f_y (d - d') \quad (36.19)$$

If compressive reinforcement is used in a doubly reinforced section as in Figure 36.8 for compression members, the depth of the compressive block is:

$$a = \frac{A_s f_y - A'_s f'_s}{0.85 f'_c b} \quad (36.20)$$

where b is the width of the section at the compression side, and f'_s is the stress in the compression.

36.3.2.3 Flanged Sections

For flanged sections where the neutral axis falls outside the flange:

$$M_n = (A_s - A_{sf})f_y \left(d - \frac{a}{2} \right) + A_{sf}f_y \left(d - \frac{h_f}{2} \right) \quad (36.21)$$

where:

$$A_{sf} = [0.85f'_c(b - b_w)h_f]/f_y$$

b_w = web width.

h_f = flange thickness.

The depth is:

$$a = \frac{A_s f_y}{0.85 f'_c b} > h_f \quad (36.22)$$

$$\rho_f = 0.85 f'_c (b - b_w) \frac{h_f}{f_y b_w d}$$

36.3.2.4 Minimum Reinforcement

The flexural reinforcement percentage ρ has to have a minimum value of $\rho_{\min} = 3\sqrt{f'_c}/f_y$ for positive moment reinforcement, and $\rho_{\min} = 6\sqrt{f'_c}/f_y$ for negative moment reinforcement but always not less than $200/f_y$, where f_y is in units of pounds per square inch. The factored moment is:

$$M_u = \phi M_n \quad (36.23)$$

where $\phi = 0.90$ for flexure.

36.3.3 Shear Strength

External transverse load is resisted by internal shear to maintain section equilibrium. As concrete is weak in tension, the principal tensile stress in a beam cannot exceed the tensile strength of the concrete. The principal stress is composed of two components: shear stress and flexural stress. It is important that the beam web be reinforced to prevent diagonal shear cracks from opening. The resistance of the plain concrete in the web sustains part of the shear stress, and the balance has to be borne by the diagonal tension reinforcement. The shear resistance of the plain concrete is known as the *nominal shear strength*, or V_c :

$$V_c = 2.0\lambda\sqrt{f'_c}b_w d \text{ (lb)} \leq 3.5\lambda\sqrt{f'_c} \text{ (lb)} \quad (36.24a)$$

$$V_c = \left(\frac{\lambda\sqrt{f'_c}}{6} \right) b_w d \text{ (N)} \quad (36.24b)$$

or

$$V_c = \left[1.9\lambda\sqrt{f'_c} + 2500\rho_w \frac{V_u d}{M_u} \right] b_w d \text{ (lb)} \leq 3.5\lambda\sqrt{f'_c} \text{ (lb)} \quad (36.25a)$$

$$V_c = \left[\left(\lambda\sqrt{f'_c} + 120\rho_w \frac{V_u d}{M_u} \right) / 7 \right] b_w d \text{ (N)} \quad (36.25b)$$

Values for λ are given in Section 36.1.

$$\rho_w = \frac{A_s}{b_w d} \quad \text{and} \quad \frac{V_u d}{M_u} \leq 1.0$$

No web steel is needed if $V_u < 1/2 V_c$. For calculating V_n , the critical section is at a distance d from the support face. Spacing of the web stirrups is as follows:

$$s = \frac{A_v f_y d}{V_u / \phi - V_c} \quad (36.26)$$

where A_v is the cross-sectional area of web steel, and ϕ is 0.85 for shear and torsion. The transverse web steel is designed to carry the shear load $V_s = V_n - V_c$. The spacing of the stirrups is governed by the following:

$$V_s \geq 4\lambda\sqrt{f'_c} : s = \frac{d}{4}$$

$$V_s \leq 2\lambda\sqrt{f'_c} : s = \frac{d}{2}$$

$$V_s \geq 8\lambda\sqrt{f'_c} : \text{enlarge section}$$

The minimum sectional area of the stirrups is $A_{v,\min} = 50b_w s / f_y$; $s_{\max} = d/2$ where shear is to be considered; d is the effective depth to the center of the tensile reinforcement; and f_y is the yield strength of the steel (lb/in.²).

36.3.4 Strut-and-Tie Theory and Design of Corbels and Deep Beams

36.3.4.1 Strut-and-Tie Mechanism

As an alternative to the usual approach where plane sections before bending are considered to remain plane after bending, the strut-and-tie model is applied effectively in regions of discontinuity. These regions could be the support sections in a beam, the zones of load application, or the discontinuity caused by abrupt changes in section, such as brackets, beam daps, pile caps cast with column sections, portal frames, and others. Consequently, structural elements can be divided into segments called *B-regions*, where the standard beam theory applies with the assumption of linear strains, and *D-regions*, where the plane sections hypothesis is no longer applicable.

The analysis essentially follows the truss analogy approach, where parallel **inclined cracks** are assumed and expected to form in the regions of high shear. The concrete between the inclined cracks carries inclined compressive forces acting as diagonal compressive struts. The provision of transverse stirrups along the beam span results in a truss-like action where the longitudinal steel provides the tension chord of the truss as a tie, hence the “strut-and-tie” expression. Depending on the interpretation of the designer, simplifications of the paths of forces that are chosen to represent the real structure can considerably differ; consequently, this approach is more an art than an engineering science in the selection of the models, and significant over-design and serviceability checks become necessary. For equilibrium, at least three forces have to act at a joint, termed the *node*. Figure 36.9 demonstrates the simplified truss model for simply supported deep beams loaded on the top fibers, and Figure 36.10 shows a continuous beam model, as presented in the ACI 318 Code, both outlining the compression struts, the tension ties, and the nodes at the D regions which are the points of load application, discontinuity, and the support regions. Naturally, other possible alternative models can also be used, provided that they satisfy equilibrium and compatibility.

FIGURE 36.9 Strut-and-tie model of simply supported deep beam subjected to concentrated load on top. (From ACI Committee 318, *Building Code Requirements for Structural Concrete*, ACI 318; *Commentary*. ACI 318R-08, American Concrete Institute, Farmington Hills, MI, 2008.)

36.3.4.2 ACI Design Requirements by the Strut-and-Tie Method

Nodal Forces:

$$\phi F_n \geq F_u \quad (36.27)$$

where:

F_n = nominal strength of a strut, tie, or nodal zone (lb).

F_u = factored force acting on a strut, tie, bearing area, or nodal zone (lb).

ϕ = for both struts and ties (similar to the strength reduction for shear).

Strength of Struts

$$F_{ns} = f_{ce} A_{cs} \quad (36.28)$$

where:

F_{ns} = nominal strength of strut (lb).

A_{cs} = effective cross-sectional area at one end of a strut, taken perpendicular to the axis of the strut (in.²).

f_{ce} = effective compressive strength of the concrete in a strut or nodal zone (psi).

$$f_{ce} = 0.85\beta f'_c \quad (36.29)$$

where:

β = 1.0 for struts that have the same cross-sectional area of the midstrut cross-section in the case of bubble struts.

β = 0.75 for struts with reinforcement resisting transverse tensile forces.

β = 0.40 for struts in tension members or tension flanges.

β = 0.60 all other cases.

FIGURE 36.10 Typical strut-and-tie model of continuous deep beam subjected to concentrated load on top. (From ACI Committee 318, *Building Code Requirements for Structural Concrete*, ACI 318; *Commentary*. ACI 318R-08, American Concrete Institute, Farmington Hills, MI, 2008.)

Longitudinal Reinforcement

$$F_{ns} = f_{ce}A_{cs} + A'_s f'_s \quad (36.30)$$

where:

A'_s = area of compression reinforcement in a strut (in.²).

f'_c = stress in compression reinforcement (in.²).

Strength of Ties

$$F_{nt} A_{st} f_y + A_{ps} (f_{pe} + \Delta f_{ps}) \quad (36.31)$$

where:

F_{nt} = nominal strength of tie (lb).

A_{st} = area of non-prestressed reinforcement in a tie (in.²).

A_{ps} = area of prestressing reinforcement (in.²).

f_{pe} = effective stress after losses in prestressing reinforcement.

Δf_{ps} = increase in prestressing stress beyond the service load level.

$f_{pe} + \Delta f_{ps}$ should not exceed f_{py} .

When no prestressing reinforcement is used, $A_{ps} = 0$ in Equation 36.31.

$$h_{t,\max} = F_{nt} / f_{ce} \quad (36.32)$$

where $h_{t,\max}$ is the maximum effective height of concrete concentric with the tie, used to dimension the nodal zone (in.). If the bars in the tie are in one layer, the effective height of the tie can be taken as the diameter of the bars in the tie plus twice the cover to the surface of the bars. The reinforcement in the ties has to be anchored by hooks, mechanical anchorages, post-tensioning anchors, or straight bars, all with full development length.

Strength of Nodal Zones

$$F_{nm} = f_{ce} A_n \quad (36.33)$$

where:

F_{nm} = nominal strength of a face of a nodal zone (lb).

A_n = area of the face of a nodal zone or a section through a nodal zone (in.²).

It can be assumed that the principal stresses in the struts and ties act parallel to the axes of the struts and ties. Under such a condition, the stresses on faces perpendicular to these axes are principal stresses.

Confinement in the Nodal Zone

The ACI 318 Code stipulates that, unless confining reinforcement is provided within the nodal zone and its effect is supported by analysis and experimentation, the computed compressive stress on a face of a nodal zone due to the strut and tie forces should not exceed the values given by Equation 36.34:

$$f_{ce} = 0.85 \beta_n f'_c \quad (36.34)$$

where:

$\beta_n = 1.0$ in nodal zones bounded by struts or bearing stresses.

$\beta_n = 0.8$ in nodal zones anchoring one tie.

$\beta_n = 0.6$ in nodal zones anchoring two or more ties.

For detailed design examples, refer to Nawy (2008).

36.3.4.3 Design Example of a Corbel by the Strut-and-Tie Method

Design a corbel to support a factored vertical load $V_u = 80,000$ lb (160 kN) acting at a distance $a_v = 5$ in. (127 mm) from the face of the column. It has width $b = 10$ in. (254 mm), total depth $h = 18$ in. (457 mm), and an effective depth $d = 14$ in. (356 mm) (Nawy, 2008). Given:

$f'_c = 5000$ psi (34.5 MPa) for normal weight concrete.

$f_y = f_{yt} = 60,000$ psi (414 MPa).

The supporting column size is 12×14 in. Assume the corbel is to be monolithically cast with the column, and neglect the weight of the corbel in the computations.

Solution

1. Assume that the corbel is monolithically cast with the column. Total depth $h = 18$ in. and effective depth $d = 14$ in. are based on the requirement that the vertical dimension of the corbel outside the bearing area must be at least one half the column face width of 14 in. (column size, 12×14 in.). Select a simple strut-and-tie model as shown in Figure 36.11, assuming that the center of tie AB is located at a distance of 4 in. below the top extreme corbel fibers, using one layer of reinforcing bars. Also assume that horizontal tie DG lies on a horizontal line passing at the re-entrant corner C of the corbel. The solid lines in Figure 36.11 denote tension tie action (T), and the dashed lines denote compression strut action (C). The nodal points A, B, C, and D result from the selected strut-and-tie model. Note that the entire corbel is a D-region structure because of the existing statics discontinuities in the geometry of the corbel and the vertical and horizontal loads.

FIGURE 36.11 Strut and tie forced in corbel design example. (From Nawy, E.G., *Prestressed Concrete: A Fundamental Approach*, 5th ed., Prentice Hall, Upper Saddle River, NJ, 2006.)

- The strut and tie truss forces are $N_{uc} = 0.20$ and $V_u = 16,000$ lb. The following are the truss member forces calculated from statics in Figure 36.11.

Compression strut BC:

$$\text{Length } BC = \sqrt{(7)^2 + (14)^2} = 15.652 \text{ in.}$$

$$F_{BC} = 80,000 \times \frac{15.652}{14} = 89,443 \text{ lb}$$

Tension tie BA:

$$F_{BA} = 80,000 \times \frac{7}{14} + 16,000 = 56,000 \text{ lb}$$

Compression strut AC:

$$F_{AC} = \frac{56,000\sqrt{(8)^2 + (14)^2}}{8} = 112,872 \text{ lb}$$

Tension tie AD:

$$F_{AD} = \frac{112,872 \times 14}{\sqrt{(8)^2 + (14)^2}} = 98,000 \text{ lb}$$

Compression strut CC':

$$F_{CC'} = 80,000 + 98,000 = 178,000 \text{ lb.}$$

Tension tie CD:

$$F_{CD} = 56,000 - 40,000 = 16,000 \text{ lb}$$

Steel bearing plate design:

$f_{ce} = \phi(0.85f'_c)$, where $\phi = 0.75$ for bearing in strut-and-tie models.

$$\text{Area of plate is } A_1 = \frac{80,000}{0.75(0.85f'_c)} = \frac{80,000}{0.75 \times 0.85 \times 5000} = 25.10 \text{ in.}^2$$

Use a 5-1/2 × 5-1/2-in. plate and select a thickness to produce a rigid plate.

Tie reinforcement design:

$$A_{ts,AB} = \frac{56,000}{\phi f_y} = \frac{56,000}{0.75 \times 60,000} = 1.25 \text{ in.}^2$$

Use three #6 bars = 1.32 in.² or, conservatively, three #7 bars = 1.80 in.² These top bars in one layer have to be fully developed along the longitudinal column reinforcement:

$$A_{ts,CD} = \frac{16,000}{0.75 \times 60,000} = 0.36 \text{ in.}^2$$

Use two #6 tie bars = 0.88 in.² to form part of the cage shown in Figure 36.12.

Horizontal reinforcement A_h for crack control of shear cracks:

$$A_h = 0.50(A_{sc} - A_n)$$

where A_n is the reinforcement resisting the frictional force N_{ue} .

$$A_n = \frac{N_{ue}}{\phi f_y} = \frac{16,000}{0.75 \times 60,000} = 0.36 \text{ in.}^2$$

Hence, $A_h = 0.50(1.25 - 0.36) = 0.45 \text{ in.}^2$. Three #3 closed ties, evenly spaced vertically as shown in Figure 36.12, give $A_h = 3(2 \times 0.11) = 0.66 \text{ in.}^2 > 0.45 \text{ in.}^2$. Because $\beta_s = 0.75$ is used for calculating the effective concrete compressive strength in the struts in the following section, where $f_{cu} = 0.85\beta_s f'_c$, the minimum reinforcement provided also has to satisfy:

$$\sum \frac{A_h / \text{tie}}{bs_t} \sin \gamma_t \geq 0.003 = \frac{2(0.11)}{14 \times 3.0} \sin 60^\circ 15' = 0.0045 > 0.003$$

Hence, adopt three #3 closed ties at 3.0-in. center-to-center spacing.

FIGURE 36.12 Corbel shear reinforcement details. (From Nawy, E.G., *Prestressed Concrete: A Fundamental Approach*, 5th ed., Prentice Hall, Upper Saddle River, NJ, 2006.)

Strut capacity evaluation:

Strut CC' —The width (w_s) of nodal zone C has to satisfy the allowable stress limit on the nodal zones, namely node B below the bearing plate and node C in the re-entrant corner to the column. Both nodes are considered unconfined.

$$F_{uCC'} \text{ for } \left(10 - \frac{w_s}{2}\right) = 80^k(5+10) + 16 \times 18 \text{ to give } \frac{w_s}{2} = 1.64 \text{ in.}$$

hence, strut width $w_s = 3.28$ in. fits within the available concrete dimension about the strut center line.

Strut BC —Nominal strength is limited to $F_{ns} = f_{ce}A_{cs}$, where $f_{ce} = 0.85\beta_s f'_c$; thus, $f_{ce} = 0.85 \times 0.75 \times 5000 = 3188$ psi = 3.188 ksi. A_{cs} is the smaller strut cross-sectional area at the two ends of the strut, namely at node C, while at node B, the node width can be assumed equal to the steel plate width of 5.50 in. A_c at node C = $14 \times 3.28 = 45.92$ in.². Available factored $F_{us,C} = \phi F_{ns,C} = 0.75 \times 3.188 \times 45.92 = 109.8$ kip, which is greater than the required $F_{BC} = 89.4$ kip.

Strut AC

$$\text{Required width } (w_s) \text{ of strut } A_c = \frac{F_{u,AC}}{\phi f_{cu} b} = \frac{112.87 \text{ kip}}{0.75 \times 3.188 \times 14} = 3.37 \text{ in.}$$

Examination of the corbel and the column depth of 12 in. suggest a minimum clear cover of 2.0 in. from the outer concrete surface; hence, the widths (w_s) of all struts fit within the corbel geometry. Adopt the design as shown in Figure 36.12.

36.3.5 Torsional Strength

The space truss analogy theory is used for the analysis and design of concrete members subjected to torsion. It is based on the shear flow in a hollow tube concept and the summation of the forces in the space truss elements (ACI Committee 318, 2008; Hsu, 1993; Nawy, 2002, 2006, 2008). ACI 318 stipulates disregarding the concrete nominal strength T_c in torsion and assigning all the torque to the longitudinal reinforcement (A_ℓ) and the transverse reinforcement (A_t), essentially assuming that the volume of the longitudinal bars is equivalent to the volume of the closed transverse hoops or stirrups. The critical section is taken at a distance d from the face of the support for the purpose of calculating torque T_u . Sections that are subjected to combined torsion and shear should be designed for torsion if the factored torsional moment (T_u) exceeds the following value for nonprestressed members:

$$T_u > \phi \lambda \sqrt{f'_c} \left(\frac{A_{cp}^2}{p_{cp}} \right) \quad (36.35)$$

where:

A_{cp} = area enclosed by the outside perimeter of the concrete cross-section.

p_{cp} = outside perimeter of the cross-section (A_{cp}) (in.).

Two types of torsion are considered: (1) *equilibrium torsion*, where no redistribution of torsional moment is possible—in this case, all the factored torsional moment is designed for; and (2) *compatibility torsion*, where redistribution of the torsional moment occurs in a continuous floor system—in this case, the maximum torsional moment to be provided for is:

$$T_u = \phi 4 \lambda \sqrt{f'_c} \left(\frac{A_{cp}^2}{p_{cp}} \right) \quad (36.36)$$

The concrete section has to be enlarged if:

$$\sqrt{\left(\frac{V_u}{b_w d} \right)^2 + \left(\frac{T_u p_h}{1.7 A_{oh}} \right)^2} \geq \phi \left(\frac{V_c}{b_w d} \right) + 8 \lambda \sqrt{f'_c} \quad (36.37)$$

where:

p_h = perimeter of centerline of outermost closed transverse torsional reinforcement (in.).

A_{oh} = area enclosed by centerline of the outermost closed transverse torsional reinforcement (in.²).

The transverse torsional reinforcement should be chosen with such size and spacing s that:

$$\frac{A_t}{2} = \frac{T_n}{2 A_o f_y \cot \theta} \quad (36.38)$$

where:

A_o = gross area enclosed by the shear path = $0.85 A_{oh}$.

θ = angle of compression diagonals (45° in reinforced concrete, 37.5° in prestressed concrete).

The longitudinal torsional reinforcement (A_ℓ) divided equally along the four faces of the beam is:

$$A_t = \frac{A_t}{s} p_h \left(\frac{f_{yv}}{f_{y\ell}} \right) \cot^2 \theta \quad (36.39)$$

$$A_{\ell, \min} = \frac{5 \sqrt{f'_c} A_{cp}}{f_{y\ell}} - \left(\frac{A_t}{s} \right) p_h \frac{f_{yv}}{f_{y\ell}} \quad (36.40)$$

where:

f_{yv} = yield strength of the transverse reinforcement.

$f_{y\ell}$ = yield strength of the longitudinal reinforcement.

The minimum area of transverse reinforcement is:

$$A_v + 2A_t \geq \frac{50b_ws}{f_y} \quad (36.41)$$

Maximum s is 12 in.

In SI units, the following are equivalent expressions:

Equation 36.35:

$$T_u = \frac{\phi\lambda\sqrt{f'_c}}{12} \left(\frac{A_{cp}^2}{P_{cp}} \right)$$

Equation 36.36:

$$T_u = \frac{\phi\lambda\sqrt{f'_c}}{3} \left(\frac{A_{cp}^2}{P_{cp}} \right)$$

For Equation 36.37, the right-hand expression is:

$$\phi \left(\frac{V_c}{b_w d} \right) + \left(\frac{8\lambda\sqrt{f'_c}}{12} \right) \text{ MPa}$$

For Equation 36.40:

$$A_{\ell, \min} = \frac{5\sqrt{f'_c}A_{cp}}{12f_{y\ell}} - \left(\frac{A_t}{s} \right) p_h \left(\frac{f_{yv}}{f_{y\ell}} \right)$$

For Equation 36.41:

$$A_v + 2A_t \geq \frac{0.35b_ws}{f_y}$$

where f_y is in megapascals. Maximum s is 300 mm.

36.3.6 Compression Members: Columns

36.3.6.1 Nonslender Columns

Columns normally fall within the *compression-controlled* zone of Figure 36.6—namely, in the strain limit condition of $\epsilon_t = 0.002$ or less at the extreme tension steel reinforcement level. The three modes of failure at the ultimate load state in columns can be summarized as follows:

- Tension-controlled state, by the initial yielding of the reinforcement at the tension side at $c/d_t = 0.375$
- Transition state denoted by the initial yielding of the reinforcement at the tension side but with a strain ϵ_t less than 0.005 but greater than the balancing strain $\epsilon_t = 0.002$ for Grade 60 steel, or $\epsilon_t = f_y/E_s$ for other reinforcement grades
- Compression-controlled state by initial crushing of the concrete at the compression face, where the *balanced strain* state occurs when failure develops simultaneously in tension and compression, a condition defined by the strain state $\epsilon_t = \epsilon_y$ at the tension reinforcement at a strain level $\epsilon_t = 0.002$ or less for Grade 60 steel

If P_{nb} is the axial load corresponding to the balanced limit strain condition—namely, when concrete at the compression face crushes simultaneously with the yielding of the extreme reinforcement at the tension face, then the modes of failure at ultimate load can also be defined as follows, where e_b is the eccentricity of the load at the balanced strain condition:

$$P_n < P_{nb}, \text{ tension failure } (e > e_b)$$

$$P_n = P_{nb}, \text{ balanced failure } (e = e_b)$$

$$P_n > P_{nb}, \text{ compression failure } (e < e_b)$$

In all of these cases, the strain-compatibility relationship must be maintained at all times through computation of the strain ϵ_s' in the compression side reinforcement on the basis of linearity of distribution of strain across the concrete section depth. It should be noted that, for each limit strain case, there are unique values of nominal thrust P_n and nominal moment M_n . Consequently, a unique eccentricity $e = M_n/P_n$ can be determined for each case. The expressions for load and moment for the balanced strain condition are:

$$P_{nb} = 0.85f_c b a_b + A_s' f_s' - A_s' f_y' \quad (36.42)$$

$$M_{nb} = P_{nb} e_b = 0.85f_c b a_b \left(y - \frac{a_b}{2} \right) + A_s' f_s' (y - d') + A_s f_y (d - y) \quad (36.43)$$

where:

$$f_s' = E_s \left[\frac{0.003(c - d')}{c} \right] \leq f_y \quad (36.44)$$

The force P_n and the moment M_n at the ultimate for any other eccentricity level are:

$$P_n = 0.85f_c b a + A_s' f_s' - A_s f_y \quad (36.45)$$

$$M_n = P_n e = 0.85f_c b a \left(\bar{y} - \frac{a}{2} \right) + A_s' f_s' (\bar{y} - d') + A_s f_y (d - \bar{y}) \quad (36.46)$$

where:

$$f_s = E_s \left[\frac{0.003(d - c)}{c} \right] \leq f_y \quad (36.47)$$

and

$\frac{c}{\bar{y}}$ = depth to the neutral axis.

\bar{y} = distance from the compression extreme fibers to the center of gravity of the section.

a = depth of the equivalent rectangular block = $\beta_1 c$, where β_1 is defined in Equation 36.18b.

The geometry of the compression member section and the forces acting on the section are shown in Figure 36.7. Equation 36.45 and Equation 36.46 are obtained from the equilibrium of forces and moments.

36.3.6.2 Slender Columns

If the compression member is slender—namely, the slenderness ratio kl_u/r exceeds 22 for unbraced members and $(34 - 12 \times M_1/M_2)$ for braced members—then failure will occur by buckling and not by material failure. In such a case, if kl_u/r is less than 100, then a first-order analysis such as the moment magnification method can be performed. If $kl_u/r > 100$, then the $P - \Delta$ effects have to be considered and a second-order analysis has to be performed. The latter is a lengthy process and is more reasonably executed using readily available computer programs.

Moment Magnification Solution ($kl_u/r < 100$)

The larger moment M_2 is magnified such that:

$$M_c = \delta_{ns} M_2 \quad (36.48)$$

where δ_{ns} is the magnification factor. The column is then designed for a moment M_c as a nonslender column. The subscript ns is non-sidesway; s is sidesway:

$$\delta_{ns} = \frac{C_m}{1 - (P_u / 0.75P_c)} \geq 1.0 \quad (36.49)$$

$$P_c = \frac{\pi^2 EI}{(k\ell_u)^2} \quad (36.50)$$

EI should be taken as:

$$EI = \frac{0.2E_c I_g + E_s I_{se}}{1 + \beta_d} \quad (36.51)$$

or

$$EI = \frac{0.4E_c I_g}{1 + \beta_d} \quad (36.52)$$

$$C_m = 0.6 + 0.4 \frac{M_1}{M_2} \geq 0.4 \quad (36.53)$$

If there is side-sway,

$$C_m = 0.6 + 0.4 \frac{M_1}{M_2} \geq 0.4 \quad (36.54a)$$

$$M_2 = M_{2ns} + \delta_s M_{2s} \quad (36.54b)$$

where:

$$\delta_s M_s = \frac{M_s}{1 - \frac{\Sigma P_u}{0.75P_c}} \geq M_s \quad (36.55a)$$

$$\delta_s M_s = \frac{M_s}{1 - Q} \geq M_s \quad (36.55b)$$

where:

$$\text{Stability index } Q = \frac{\Sigma P_u \Delta_o}{V_{us} l_c} \leq 0.05 \quad (36.55c)$$

and

Δ_o = first-order relative lateral deflection between the top and bottom of that story due to factored horizontal total shear (V_{uc}) of that story.

l_c = length of compression member.

The non-sway moment M_{2ns} is unmagnified, provided that the maximum moment is along the column height and not at its ends; otherwise, its value has to be multiplied by the non-sway magnifier δ_{ns} . If the stability index exceeds a value of 0.05, a second-order analysis becomes necessary. Effective length factor k when there is single curvature can be obtained from Figure 36.13a. For double curvature, length factor k can be obtained from Figure 36.13b. Discussion of the P-delta effect and the second-order analysis is given in Nawy, (2008).

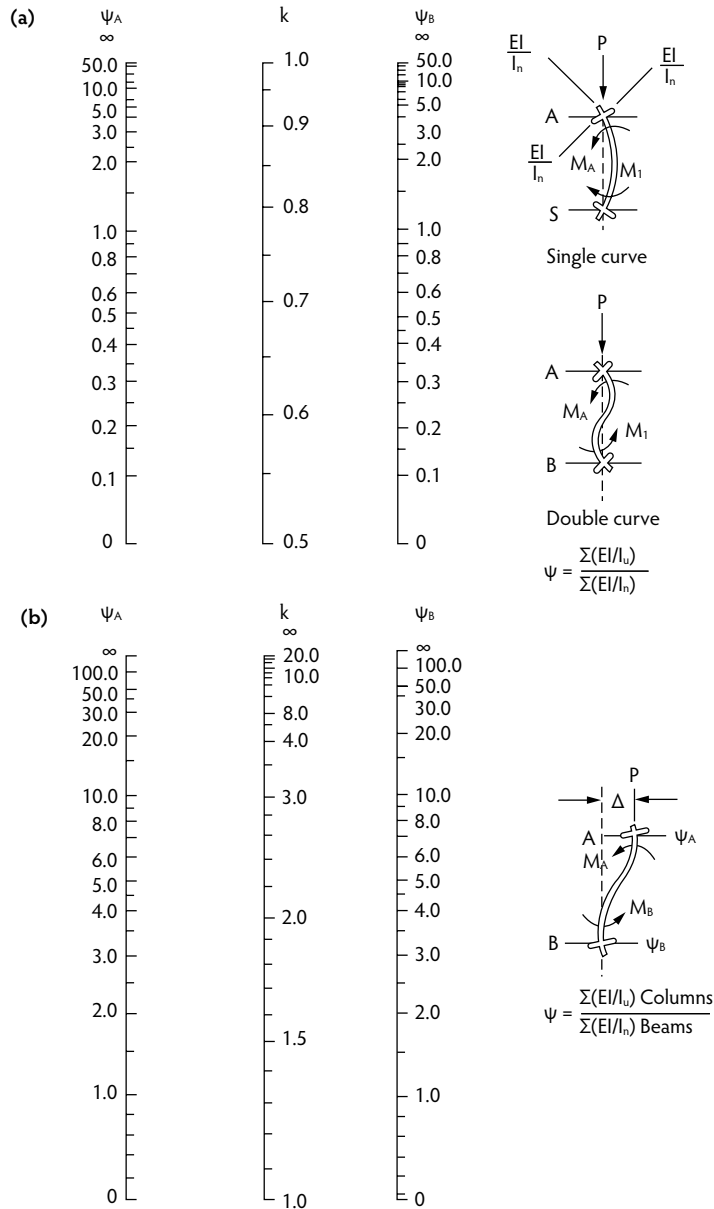

FIGURE 36.13 Slender columns end effect factor k : (a) nonsway frames; (b) sway frames. (From ACI Committee 318, *Building Code Requirements for Structural Concrete*, ACI 318-08; *Commentary*. ACI 318R-08, American Concrete Institute, Farmington Hills, MI, 2008.)

36.3.7 Two-Way Slabs and Plates

Methods for designing two-way concrete slabs and plates include:

- ACI direct design method
- ACI equivalent frame method where effects of lateral loads can be considered
- Yield line theory
- Strip method
- Elastic solutions

TABLE 36.3 Minimum Thickness of Slabs without Interior Beams, $\alpha_m = 0$

Yield Strength (f_y) (psi)	Without Drop Panels			With Drop Panels		
	Exterior Panels		Interior Panels	Exterior Panels		Interior Panels
	Without Edge Beams	With Edge Beams		Without Edge Beams	With Edge Beams	
40,000	$\ell_n/33$	$\ell_n/36$	$\ell_n/36$	$\ell_n/36$	$\ell_n/40$	$\ell_n/40$
60,000	$\ell_n/30$	$\ell_n/33$	$\ell_n/33$	$\ell_n/33$	$\ell_n/36$	$\ell_n/36$
75,000	$\ell_n/28$	$\ell_n/31$	$\ell_n/31$	$\ell_n/31$	$\ell_n/34$	$\ell_n/34$

Note: ℓ_n = effective span.

The subject is too extensive to cover in this overview; however, the important concept of serviceability as controlled by deflection and cracking limitation is briefly presented.

36.3.7.1 Deflection Control

The thickness of two-way slabs for deflection control should be determined as follows:

Flat Plate

Use Table 36.3.

Slab on Beams

If $\alpha_m \leq 0.2$, use:

$$\alpha_m > 0.2 < 2.0, \quad h \geq \frac{\ell_n (0.8 + f_y / 200,000)}{36 + 5\beta (\alpha_m - 0.2)} \quad (36.56)$$

but slab or plate thickness cannot be less than 5.0 in., so:

$$\alpha_m > 2.0, \quad \frac{(\ell_n 0.8 + f_y / 200,000)}{36 + 9\beta} \quad (36.57)$$

where:

α_m = average value of α for all beams on edges of a panel.

α = (flexural stiffness of beam section)/(flexural thickness of slab width bounded laterally by the center line of the adjacent panels on each side of the beam).

β = aspect ratio (long span/short span).

36.3.7.2 Crack Control

For crack control in two-way slabs and plates, the maximum computed weighted crack width due to flexural load (ACI Committee 224, 2001; Nawy, 2008) is as follows, where the parameter under the radical is the grid index (G_I):

$$w_{\max} \text{ (in.)} = k\beta f_s \sqrt{\frac{s_1 s_2 d_c}{d_b} \cdot \frac{8}{\pi}} \quad (36.58)$$

For w_{\max} (mm), multiply Equation 36.58 by 0.145 and use megapascals for f_s . Also,

k = fracture coefficient.

= 2.8×10^{-5} for a square uniformly loaded slab.

= 2.1×10^{-5} when the aspect ratio of short span/long span < 0.75 but > 0.5 , or for a concentrated load.

= 1.6×10^{-5} for aspect ratio less than 0.5.

β = $1.25 = (h - c)/(d - c)$, where c = depth to neutral axis.

f_s = $0.40f_y$ (kip/in²).

- h = total slab or plate thickness.
 s = spacing in direction 1 closest to the tensile extreme fibers (in.).
 s_2 = spacing in the perpendicular direction (in.).
 d_c = concrete cover to centroid of reinforcement (in.).
 d_b = diameter of the reinforcement in direction 1 closest to the concrete outer fibers (in.).

The tolerable crack widths in concrete elements are given in Table 36.1. In SI units, Equation 36.58 therefore becomes:

$$w_{\max} (\text{mm}) = 0.14k\beta f_s \sqrt{G_1}$$

where f_s is in megapascals, and s_1 , s_2 , d_c , and d_{b1} are in millimeters.

36.3.8 Development of Reinforcement

36.3.8.1 Development of Deformed Bars in Tension

The full development length (ℓ_d) for deformed bars or wires is obtained by applying multipliers to a basic theoretical development length (ℓ_{db}) in terms of the bar diameter (d_b) and other multipliers as follows:

$$\frac{\ell_d}{d_b} = \frac{3}{40} \frac{f_y}{\sqrt{f'_c}} \frac{\psi_l \psi_e \psi_s}{\left(\frac{c_b + K_{tr}}{d_b} \right)} \quad (36.59)$$

The value of $\sqrt{f'_c}$ should not exceed 100 psi (≤ 6.9 MPa) in all computations.

36.3.8.2 Modifying Multipliers of Development Length for Bars in Tension

- ψ_l = **bar location factor**. For horizontal reinforcement, when more than 12 in. of fresh concrete is below the development length or splice (top reinforcement), α is 1.3; for other reinforcement, α is 1.0.
- ψ_e = **coating factor**. For epoxy-coated bars or wires with cover less than $3d_b$ or clear spacing less than $3d_b$, β is 1.5; for all other epoxy-coated bars or wires, ψ_e is 1.2; for uncoated reinforcement ψ_e is 1.0. However, the product $\psi_l \psi_e$ should not exceed 1.7.
- ψ_s = **bar size factor**. For No. 6 and smaller bars and deformed wires (No. 20 and smaller, SI), γ is 0.8; for No. 7 and larger bars (No. 25 and larger, SI), γ is 1.0.
- c = **spacing or cover dimension** (in.). Use the smaller of either the distance from the center of the bar to the nearest concrete surface or one half the center-to-center spacing of the bars being developed.
- K_{tr} = **transverse reinforcement index**, which is equal to $(40A_{tr}/sn)$, where A_{tr} = total cross-sectional area of all transverse reinforcement within ℓ_d that crosses the potential plane of splitting adjacent to the reinforcement being developed (in.²). Also, f_{yt} = 60,000 psi is the strength value used in the development of the A_{tr} expression; s is the maximum spacing of transverse reinforcement within ℓ_d , center-to-center (in.) (mm); and n is the number of bars or wires being developed along the plane of splitting. The ACI 318 Code permits using K_{tr} as a conservative design simplification even if transverse reinforcement is present.
- λ = **lightweight-aggregate concrete factor**. When lightweight aggregate concrete is used λ is 0.75; however, when f_{ct} is specified, use $\lambda = 6.7 \sqrt{f'_c} / f_{ct}$. For all other concrete, λ is 1.0. The minimum development length in all cases is 12 in.
- λ_s = **excess reinforcement factor**. ACI 318 permits the reduction of ℓ_d if the longitudinal flexural reinforcement is in excess of that required by analysis except where anchorage or development for f_y is specifically required or the reinforcement is designed for seismic effects. The reduction multiplier $\lambda_s = (A_s \text{ required}) / (A_s \text{ provided})$ and $\lambda_{s2} = f_y / 60,000$ for cases where $f_y > 60,000$ psi. In lieu of using a refined computation for the development length of Equation 36.59, Table 36.4 can be utilized for typical construction practices by using a value of ψ_l and $\psi_e = 1.0$ and $f'_c = 4000$ psi.

TABLE 36.4a Simplified Development Length ℓ_d Equations

	#6 and Smaller Bars and Deformed Wires	#7 and Larger Bars
Clear spacing of bars being developed or spliced not less than d_b , clear cover not less than d_b , and stirrups or ties throughout ℓ_d not less than the Code minimum	$\frac{\ell_d}{d_b} = \frac{f_y \Psi_t \Psi_e}{25 \sqrt{f'_c}}$	$\frac{\ell_d}{d_b} = \frac{f_y \Psi_t \Psi_e}{20 \sqrt{f'_c}}$
or	when:	when:
Clear spacing of bars being developed or spliced not less than $2d_b$ and clear cover not less than d_b	$f'_c = 4000$ psi $\Psi_t, \Psi_e, \lambda, \lambda_s, \gamma = 1.0$ $\Psi_s = 0.8$ $\ell_d = 38d_b$	$f'_c = 4000$ psi $\Psi_t, \Psi_e, \Psi_s, \lambda, \lambda_s, \gamma = 1.0$ $\ell_d = (38/0.8)d_b = 48d_b$
Other cases	$\frac{\ell_d}{d_b} = \frac{3f_y \Psi_t \Psi_e}{50 \sqrt{f'_c}}$ $\ell_d = 57d_b$	$\frac{\ell_d}{d_b} = \frac{3f_y \Psi_t \Psi_e}{40 \sqrt{f'_c}}$ $\ell_d = 72d_b$

Note: This is a general table for usual construction conditions giving the required development length for deformed bars of sizes No. 3 to No. 18.

Source: Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.

TABLE 36.4b SI Development Length Simplified Expressions

\leq No. 20	\geq No. 25
$\frac{\ell_d}{d_b} = \frac{f_y \Psi_t \Psi_e}{2 \sqrt{f'_c}}$	$\frac{\ell_d}{d_b} = \frac{5f_y \Psi_t \Psi_e}{8 \sqrt{f'_c}}$
$\frac{\ell_d}{d_b} = \frac{3f_y \Psi_t \Psi_e}{4 \sqrt{f'_c}}$	$\frac{\ell_d}{d_b} = \frac{15f_y \Psi_t \Psi_e}{16 \sqrt{f'_c}}$

Table 36.5 gives minimum development length ℓ_d (in.) in lieu of calculations using Table 36.4. In these two tables, the following assumptions are made: (1) The side cover is 1.5 in. on each side; (2) No. 3 stirrups are used for bars No. 11 or smaller; (3) No. 4 stirrups are used for bars No. 14 or No. 18; and (4) stirrups are bent around four bar diameters, so the distance from the centroid of the bar nearest the side face of the beam to the inside face of the No. 3 stirrup is taken as 0.75 in. for bars No. 11 or smaller and is equal to the longitudinal bar radius for No. 14 and No. 18 bars.

36.3.8.3 Development of Deformed Bars in Compression and the Modifying Multipliers

Bars in compression require shorter development length than bars in tension. This is due to the absence of the weakening effect of the tensile cracks; hence, the expression for the basic development length is:

$$\ell_{dc} = 0.02 \frac{d_b f_y}{\lambda_s \sqrt{f'_c}} \quad (36.60a)$$

$$\ell_{dc} = 0.0003 d_b f_y \quad (36.60b)$$

with the modifying multiplier for (1) excess reinforcement, $\lambda_s = (A_s \text{ required})/(A_s \text{ provided})$; and (2) spirally enclosed reinforcement, $\lambda_{s1} = 0.75$.

TABLE 36.5 Tension Reinforcement and Development Length

Bar Size	Cross-Sectional Area (in. ²)	Bar Diameter (in.)	Development Length (ℓ_d) ^{a,b} (in.)	
			$s \geq 2d_b$ or d_b and Clear Cover $\geq d_b$	Other
			$\leq \#6, \ell_d = 38d_b$ $\leq \#7, \ell_d = 48d_b$	$\leq \#6, \ell_d = 57d_b$ $\leq \#7, \ell_d = 72d_b$
3	0.11	0.375	15	21
4	0.20	0.500	19	29
5	0.31	0.625	24	36
6	0.44	0.750	29	43
7	0.60	0.875	42	63
8	0.79	1.000	48	72
9	1.00	1.128	54	81
10	1.27	1.270	61	92
11	1.56	1.410	68	102
14	2.25	1.693	82	122
18	4.00	2.257	108	163

^a For compression development length, ℓ_d multiplier $\times \ell_{db}$.

^b Multiply table values by $\alpha = 1.3$ for top reinforcement, $\lambda = 0.75$ for lightweight aggregate, $\psi_e = 1.5$ for epoxy-coated bars with cover less than $3d_b$ or clear spacing less than $6d_b$, and $\beta = 1.2$ for other epoxy-coated bars. Minimum ℓ_d for all cases is 12 in.

Note: For $f'_c = 4000$ psi normal weight concrete, $f_y = 60,000$ psi steel ($\psi_1, \psi_e, \lambda = 1.0$; $\gamma = 0.8$ for #6 bars or smaller and 1.0 for #7 bars and larger). For f'_c values different from 4000 psi, multiply table values by $(\sqrt{4000/f'_c})$. For $f_y = 40,000$ psi, multiply by 2/3. f' should not exceed 100.

Source: Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.

36.3.8.4 Development of Bundled Bars in Tension and Compression

If bundled bars are used in tension or compression, l_d has to be increased by 20% for three-bar bundles and 33% for four-bar bundles, and f'_c should not be taken as greater than 100 psi. A unit of bundled bars is treated as a single bar of a diameter derived from the equivalent total area for the purpose of determining the modifying factors. Although the splice and development lengths of bundled bars are based on the diameter of individual bars increased by 20 or 33% as applicable, it is necessary to use an equivalent diameter of the entire bundle derived from the equivalent total area of bars when determining the factors that consider cover and clear spacing and represent the tendency of concrete to split.

36.3.8.5 SI/Metric Conversion

Where f_{yp} is in megapascals, Equation 36.59 becomes:

$$\frac{15f_y\psi_1\psi_e\psi_s}{16\sqrt{f'_c}\left(\frac{c_b + K_{tr}}{d_b}\right)} \quad \text{and} \quad K_{tr} = \frac{1.6A_{tr}}{sn}$$

36.3.8.6 Development of Welded Deformed Wire Fabric in Tension

The development length (l_d) for deformed welded wire fabric should be taken as the ℓ_d value obtained from Equation 36.59 or Table 36.4 multiplied by a fabric factor. The fabric factor, with at least one cross wire within the development length and not less than 2 in. from the point of the critical section, should be taken as the greater of the following two expressions:

$$(f_y - 35,000)/f_y \quad (36.61)$$

$$5d_b/s \quad (36.62)$$

but should not be taken as greater than 1.0. Here, s is the spacing of wire to be developed or spliced (in.).

36.4 Prestressed Concrete

36.4.1 General Principles

Reinforced concrete is weak in tension but strong in compression. To maximize the utilization of its material properties, an internal compressive force is induced on the structural element through the use of highly stressed prestressing tendons to precompress the member prior to application of the external gravity live load and superimposed dead load. A typical effect of the prestressing action shown in Figure 36.14 uses a straight tendon, as is usually the case for precast elements (Nawy, 2006). For cast-in-place elements, the tendon can be either harped, or, as is usually the case, it can be draped in a parabolic form. Figure 36.15 illustrates the stress and strain distributions across the beam depth and the forces acting on the section in a prestressed concrete beam and the compressive stress block of the section.

Stresses due to initial prestressing plus self-weight:

$$f^t = \frac{P_i}{A_c} \left(1 - \frac{ec_t}{r^2} \right) - \frac{M_D}{S^t} \quad (36.63a)$$

$$f_b = -\frac{P_i}{A_c} \left(1 + \frac{ec_b}{r^2} \right) + \frac{M_D}{S_b} \quad (36.63b)$$

Stresses at service load:

$$f^t = -\frac{P_e}{A_c} \left(1 - \frac{ec_t}{r^2} \right) - \frac{M_T}{S^t} \quad (36.64a)$$

$$f_b = -\frac{P_e}{A_c} \left(1 + \frac{ec_b}{r^2} \right) + \frac{M_T}{S_b} \quad (36.64b)$$

FIGURE 36.14 Stress distribution at service load in prestressed beam with constant tendon eccentricity. (From Nawy, E.G., *Prestressed Concrete: A Fundamental Approach*, 5th ed., Prentice Hall, Upper Saddle River, NJ, 2006.)

FIGURE 36.15 Stress and strain distribution across prestressed concrete beam depth: (a) beam cross-section; (b) strain across depth; (c) actual stress block; and (d) assumed equivalent block. (From Nawy, E.G., *Prestressed Concrete: A Fundamental Approach*, 5th ed., Prentice Hall, Upper Saddle River, NJ, 2006.)

36.4.2 Minimum Section Modulus for Variable Tendon Eccentricity

$$S^t \geq \frac{(1-\gamma)M_D + M_{SD} + M_L}{\gamma f_{ti} - \gamma f_c} \quad (36.65a)$$

$$S_b \geq \frac{(1-\gamma)M_D + M_{SD} + M_L}{\gamma f_t - \gamma f_{ci}} \quad (36.65b)$$

where:

- γ = percentage loss in prestress.
- M_D = self-weight moment.
- M_{SD} = superimposed dead load moment.
- M_L = live load moment.
- f_{ti} = initial tensile stress in concrete.
- f_c = service load concrete compressive strength.
- f_t = service load concrete tensile strength.
- f_{ci} = initial compressive stress in concrete.
- S^t = section modulus at top fibers (simple span).
- S_b = section modulus at bottom fibers (simple span).

36.4.3 Minimum Section Modulus for Constant Tendon Eccentricity

$$S^t \geq \frac{M_D + M_{SD} + M_L}{\gamma f_{ti} - f_c} \quad (36.66a)$$

$$S_b \geq \frac{M_D + M_{SD} + M_L}{f_t - \gamma f_{ci}} \quad (36.66b)$$

36.4.4 Maximum Allowable Stresses

36.4.4.1 ACI 318 Code Concrete Stresses

$$f'_{ci} \equiv 0.75 f'_c \text{ psi}$$

$$f_{ci} \equiv 0.60 f'_{ci} \text{ psi}$$

$$f_{ti} = \sqrt{f'_{ci}} \text{ psi on span } \left(\sqrt{f'_{ci}} / 4 \text{ MPa} \right) = \sqrt{f'_{ci}} \text{ psi on support } \left(\sqrt{f'_{ci}} / 2 \text{ MPa} \right)$$

$$f_c = 0.45 f'_c \text{ or } 0.60 f'_c \text{ where permitted by ACI 318.}$$

$$f_t = \sqrt{f'_c} \text{ psi } \left(\sqrt{f'_c} / 2 \text{ MPa} \right) = 12 \sqrt{f'_c} \text{ psi if deflection is verified } \left(\sqrt{f'_c} / 2 \text{ MPa} \right)$$

36.4.4.2 Reinforcing Tendon Stresses

Tendon jacking:

$$f_{ps} = 0.94 f_{py} \leq 0.80 f_{pu}$$

Immediately after prestress transfer:

$$f_{ps} = 0.82 f_{pj} \leq 0.74 f_{pu}$$

Post-tensioned members at anchorage immediately after tendon anchorage:

$$f_{ps} = 0.70f_{pu}$$

where:

f_{ps} = ultimate design stress allowed in tendon.

f_{py} = yield strength of tendon.

f_{pu} = ultimate strength of tendon.

A prestressed concrete section is designed for both the service load and the ultimate load. A typical distribution of stress at service load at midspan is shown in Figure 36.15. Expressions for the ultimate load evaluation are essentially similar to those of reinforced-concrete elements, taking into consideration that both prestressing tendons and mild steel bars are used. Note the similarity between Figure 36.15 and Figure 36.7. For extensive design and analysis details, refer to Nawy (2006).

36.5 Shear and Torsion in Prestressed Elements

36.5.1 Shear Strength: ACI Short Method When $f_{pe} > 0.40f_{pu}$

The nominal shear stress of the concrete in the web is:

$$V_c \text{ (lb)} = \left(0.60\lambda\sqrt{f'_c} + \frac{700V_u d}{M_u} \right) b_w d \quad (36.67a)$$

$$V_c \geq 2\lambda\sqrt{f'_c}b_w d \leq 5\lambda\sqrt{f'_c}b_w d, \quad \frac{V_u d}{M_u} \leq 1.0$$

$$V_c \text{ (Newton)} = \left(\frac{\lambda\sqrt{f'_c}}{20} + 5 \frac{V_u d}{M_u} \right) b_w d \quad (36.67b)$$

$$V_c \geq \frac{\lambda\sqrt{f'_c}}{6} b_w d \leq 0.40\lambda\sqrt{f'_c}b_w d, \quad \frac{V_u d}{M_u} \leq 1.0$$

36.5.2 Detailed Method

The smaller of the two values obtained from flexural shear (V_{ci}) or web shear (V_{cw}) in the following expressions has to be used in the design of the web reinforcement in prestressed concrete members.

36.5.2.1 Flexural Shear

$$V_{ci} \text{ (lb)} = 0.6\lambda\sqrt{f'_c}b_w d + V_d + \frac{V_i M_{cr}}{M_{\max}} \geq 1.7\lambda\sqrt{f'_c}b_w d \quad (36.68a)$$

where:

V_{ci} = flexural shear force.

$M_{cr} = M_{cr} = S_b \left(\lambda\sqrt{f'_c} + f_{ce} - f_d \right)$.

S_b = section modulus at the extreme tensile fibers.

V_d = shear force at section due to unfactored dead load.

V_i = factored shear force due to externally applied load.

f_{ce} = compressive stress in concrete due to effective prestress only at the tension face of the section.

f_d = stress due to unfactored dead load at extreme fibers in tension.

$$V_{ci} \text{ (Newton)} = \left(\frac{\lambda \sqrt{f'_c}}{20} \right) b_w d + V_d + \frac{V_i M_{cr}}{M_{\max}} \quad (36.68b)$$

36.5.2.2 Web Shear

V_{CW} = web shear force

$$V_{CW} \text{ (lb)} = \left(3.5 \lambda \sqrt{f'_c + \bar{f}_{ce}} \right) b_w d + V_p \quad (36.69)$$

$$V_{CW} \text{ (Newton)} = \left(0.3 \lambda \sqrt{f'_c + \bar{f}_{ce}} \right) b_w d + V_p$$

where:

\bar{f}_{ce} = compressive stress at center of gravity of section due to externally applied load.

V_p = vertical component of prestressing force.

The critical section for calculating V_u and T_u is taken at distance $(h/2)$ from the face of the support.

36.5.3 Minimum Shear Reinforcement

For prestressed members subjected to shear, the minimum transverse web stirrups are the smaller of:

$$A_v \text{ (in.}^2\text{)} = \frac{50 b_w s}{f_y} \quad (36.70a)$$

or

$$A_v \text{ (in.}^2\text{)} = \frac{A_{ps} f_{pu} s}{80 f_y d} \sqrt{\frac{d_p}{b_w}} \quad (36.70b)$$

where f_y is in psi and s is the web reinforcement spacing.

36.5.4 Torsional Strength

As discussed earlier, the nominal torsional strength (T_c) is disregarded, and all of the torque is assumed by longitudinal bars and the transverse closed hoops. The expressions used in the case of prestressed concrete elements are essentially the same as those for reinforced-concrete elements with the following adjustments for Equation 36.35 and Equation 36.36. Multiply the right side by:

$$\sqrt{1 + \frac{3 f_{ce}}{\sqrt{f'_c}}}$$

For hollow sections, the left side of Equation 36.37 becomes:

$$\left(\frac{V_u}{b_w d} \right) + \left(\frac{T_u p_h}{1.7 A_{oh}^2} \right)$$

The maximum spacing of the closed hoops is $1/8 p_h \leq 12$ in., and the longitudinal bar diameter is not less than $1/16s$, where s is the spacing of the hoop steel.

36.6 Walls and Footings

The design of walls and footings should be viewed in the context of designing a one-way or two-way cantilever slab in the case of footings and one-way vertical cantilevers in the case of reinforced-concrete walls. The criteria and expressions for proportioning their geometry are the same as those presented in earlier sections of this chapter. Shear V_u in one-way footings is taken at a distance d from the face of the vertical concrete wall or columns and at $d/2$ in the case of two-way footings. The nominal shear strength (capacity) V_c of the one-way slab footing is:

$$V_c = 2\lambda\sqrt{f'_c}b_wd \quad (36.71)$$

For two-way slab footings, the nominal shear strength V_c should be the smallest of:

$$V_c = 4\lambda\sqrt{f'_c}b_o d \quad (36.72a)$$

or

$$V_c = \left(2 + \frac{4}{\beta_c}\right)\lambda\sqrt{f'_c}b_o d \quad (36.72b)$$

or

$$V_c = \left(\frac{\alpha_s d}{b_o} + 2\right)\lambda\sqrt{f'_c}b_o d \quad (36.72c)$$

where b_o is the perimeter shear failure length at distance $d/2$ from all faces of columns. If the column size is $c_1 \times c_2$, then:

$b_o = 2(c_1 + d/2) + 2(c_2 + d/2)$ for an interior column.

$\beta_c =$ ratio of long side/short side of reaction area.

$\alpha_s = 40$ for interior columns, 30 for end columns, and 20 for corner columns.

The same requirement for shear in Equation 36.72 applies to the shear design of two-way action structural slabs and plates.

Acknowledgments

This chapter is based on material appearing in the previous edition of this *Handbook*; from *Fundamentals of High-Performance Concrete*, 2nd ed., by E.G. Nawy (John Wiley & Sons, 2001); from *Reinforced Concrete: A Fundamental Approach*, 6th ed., by E.G. Nawy (Prentice Hall, 2008); from *Prestressed Concrete: A Fundamental Approach*, 5th ed., by E.G. Nawy (Prentice Hall, 2006); and from various committee reports and standards of the American Concrete Institute, Farmington Hills, MI.

- bituminous fly ash, 2-13, 2-18
- black iron oxide, 29-25
- Blaine specific-surface method, 2-5, 2-6, 2-20, 2-29
- blast-furnace slag, 1-11, 1-25, 2-18–2-27, 5-27, 5-29,
 - 6-18, 11-5, 11-16; *see also* slags
 - carbonation, and, 2-27
 - creep, and, 2-23
 - durability, and, 2-24–2-27
 - expansion, and, 2-26–2-27
 - flexural strength, and, 2-23
 - granulated, 2-19, 2-20, 2-21, 2-22, 2-23, 2-24, 2-25,
 - 5-27, 5-28, 5-41, 6-33, 6-42, 15-23, 26-2
 - hardened cement, and, 2-21–2-24
 - modulus of elasticity, and, 2-23
 - permeability, and, 2-24
 - properties of, 2-20–2-21
 - proportioning, 2-20
 - shrinkage, and, 2-23
 - strength development, 2-21
 - sulfate attack, and, 2-24–2-25
- blasting mats, 11-61
- bleeding, 2-10, 2-20, 2-33, 2-34, 2-36, 3-4, 3-6, 3-7,
 - 3-14, 3-16, 4-10, 5-2–5-6, 5-28, 5-31, 5-35,
 - 6-40, 10-3, 10-17, 11-5, 11-23, 15-3, 15-4,
 - 15-11, 20-17, 27-5, 30-57, 30-58
- blended hydraulic cements, *see* cements: blended hydraulic
- blind lifts, 19-40
- blisters, 11-41, 11-55
- bloating, of raw materials, 1-17
- blockouts, 12-8, 12-14, 20-51, 30-29
- blow holes, 30-31, 30-56, 30-73; *see also* bug holes
- blowouts, 10-34, 10-36, 12-20, 12-24–12-27, 12-39,
 - 12-42, 28-11
- Blue Ridge Parkway, 29-2, 29-9–29-10, 29-20, 29-23,
 - 29-25, 29-28
- Bob Graham Sunshine Skyway Bridge, 29-2, 29-19
- Bodkin connector, 14-51
- bolsters, 11-41, 11-42
- bolt ties, 30-39
- bolted assemblages, 34-7–34-11, 34-18–34-20
- bond, 8-41, 11-18
- bond beam, 28-3, 28-20, 28-42, 28-55
- bond breaker, 10-28, 10-29, 11-39, 11-42, 12-2,
 - 16-14, 17-6, 17-15, 30-31, 30-39, 30-73
- bond failure, 16-11, 23-5, 27-4
- bond patterns, 28-16–28-18
- bond splitting, 24-12, 24-14, 24-18, 24-19, 24-21,
 - 24-22, 25-8
- bond strength, 3-16, 8-20, 8-22–8-26, 8-41, 11-26,
 - 11-56, 16-11, 23-3, 23-4–23-13
 - overlay, 23-3, 23-4–23-13
 - revibration, and, 30-57
- bond stress, 4-25
- bonded concrete overlays, 23-1–23-16, 33-2, 33-16;
 - see also* overlays
- bonded foil gauges, 27-18
- bonded post-tensioned concrete, 16-16
- bonded prestressing, 10-38
- bonding agent, 30-70, 30-73
- boom, 19-15–19-17, 19-34, 19-44, 19-45, 19-46,
 - 20-63, 21-40
 - articulated, 19-48
 - climbing, 19-3, 19-8, 19-50
 - extension, 19-38
 - knuckle, 19-43, 19-48
 - lattice, 19-35–19-36, 19-37, 19-38, 19-40
 - length of, 19-16–19-17
 - lifts, 19-48
 - luffing, 19-37
 - placing, 19-3, 19-4, 19-7, 19-8, 19-9, 19-17, 19-18
 - location of, 19-8
 - pump, 19-15, 19-17
 - rear-mounted, 19-43
 - telescopic, 19-35–19-36, 19-37, 19-43, 19-48
 - tower-mounted, 19-15, 19-17–19-19
 - trucks, 19-43–19-44
 - Z-type, 19-17
- borax, 3-2
- borescope, 21-30
- boring, 14-28, 14-29
- bottom-dump trailers, 20-64–20-65
- bottom-founded structures, 13-2–13-9, 13-24,
 - 13-25, 13-26
- boundary elements, 32-45, 32-62
- boundary members, 32-33
- boundary representation, 18-9, 18-10
- box girders, 11-43, 11-46, 27-27, 29-2, 29-5, 29-7,
 - 29-14, 29-15, 29-17, 29-29, 29-32, 32-54
- braced frames, 10-15
- bracing, 7-3, 7-9, 7-16, 7-26, 7-27, 7-34, 7-42, 10-15,
 - 10-28, 11-31
 - concrete, 13-11
 - crane, 19-28
 - cross-, 7-43
 - demolition, and, 12-40
 - design of, 7-43, 7-46–7-48
 - diagonal, 7-16, 7-42
 - excavation, 14-55–14-56
 - for precast elements, 30-60, 30-63
 - lateral, 10-15
 - pile, 13-4
 - seismic, 34-1–34-24
 - tilt-up, 11-55

- bracketed duration, 32-3
- Bragg grating, 27-21
- Branson's creep evaluation model, 4-6, 4-7, 4-9
- Brazilian split-cylinder test, 20-27, 20-28
- breakaway parapet, 20-45
- breakers, 12-40
- break-off number, 21-15, 21-16
- break-off test, 21-15–21-16, 21-26
 - failure, 21-16
- B-regions, 36-15
- brick, 8-48, 21-18–21-19, 27-9, 28-3, 28-4–28-5, 28-11, 28-13, 28-25, 30-27, 30-71, 30-31, 31-9,
- bridge coatings, 29-25
- bridge decks, 1-22, 3-14, 3-15, 5-17, 5-25, 5-38, 6-21, 7-7, 11-12, 11-34, 13-14, 15-22, 16-4, 16-5, 21-40, 21-41, 21-42, 21-45, 21-47, 21-48, 21-61, 22-3, 22-21, 22-23, 27-25; *see also* bridges
 - chain-drag testing of, 27-6
 - engineered cementitious composite (ECC), and, 24-12, 24-27, 24-31, 24-37
 - macro texture of, 23-8–23-10
 - overlays on, 23-1–23-16
 - precast concrete, 33-2, 33-3, 33-6–33-7, 33-9–33-12
- bridge piers, 7-9, 10-34, 11-15, 11-46, 11-56, 13-9, 13-14, 14-57, 15-3, 15-7, 29-7, 29-8, 29-10, 29-12, 29-13, 29-16, 29-17, 29-21, 29-22, 29-23, 29-25, 29-26
- bridges, 10-2, 10-7, 10-13, 10-26, 11-3, 11-17, 11-18, 11-20, 11-21, 11-25, 11-30, 11-33–11-46, 13-4, 13-9, 16-16, 18-9; *see also* bridge decks, bridge piers, cantilever bridge construction
 - aesthetics of, 29-1–29-32
 - color, 29-24–29-26
 - texture, 29-24–29-26
 - alignment of, 29-5–29-6
 - cable-stayed, 13-14, 29-13–29-15, 29-30
 - cable-stayed concrete segmental, 11-40
 - cast-in-place, 7-5
 - cast-in-place cantilever segmental, 11-40–11-42
 - composite reinforced concrete, 22-19
 - conceptual design of, 29-4–29-8
 - context-sensitive design of, 29-10–29-11
 - continuous concrete slab, 27-26
 - demolition of, 11-60
 - detecting delamination in, 21-40
 - drainage for, 29-29
 - earthquake-damaged, retrofit of, 32-56–32-61
 - environmental sensitivity of, 29-9–29-11
 - float-in erection, 11-43–11-44
 - floating, 13-9, 13-14, 13-26
 - in urban environments, 29-15–29-17
 - incremental launching of, 11-43
 - inspection of, 16-3
 - lift-in erection of, 11-43–11-44
 - load testing of, 27-4
 - long-span, 11-60
 - long-span prestressed, 29-1–29-32
 - construction methods for, 29-11–29-23
 - performance evaluation of, 27-21–27-28, 27-29–27-31
 - post-tensioned precast segmental, 11-38–11-40
 - precast cantilevered segmental, 11-42–11-43
 - prefabricated elements for, 33-1–33-16
 - repair of, 16-2
 - seismic analysis/design of, 32-48–32-56

cable-stayed bridges, 13-14, 29-13–29-15, 29-30
 caissons, 10-12, 10-13, 10-14, 13-2, 13-9, 13-15, 14-57, 14-76–14-79, 15-7, 15-8, 16-22, 16-23, 16-24, 16-26, 16-27, 16-31, 16-32, 16-38, 16-39
 drilled, 16-20
 integrity of, 21-33
 lightweight aggregate concrete, 13-15
 reinforcement of, 10-14
 Calatrava, Santiago, 30-2
 calcite, 1-3, 1-20, 30-26
 calcium, 2-1, 2-2, 26-14, 30-24; *see also* fly ash:
 low-calcium
 calcium aluminate, 1-2, 1-10, 1-11, 2-15, 2-17, 2-24, 3-2, 3-6, 3-7, 3-14
 hydrates, 5-35
 calcium aluminoferrites, 1-2, 2-17
 calcium carboaluminate hydrate, 2-26
 calcium carbonate, 1-22, 2-15, 2-26, 5-10
 calcium chloride, 2-15, 3-7, 3-8, 4-11, 5-31, 6-7, 8-21, 8-22, 8-23, 12-20, 12-27, 15-17, 16-19, 35-17
 architectural concrete, and, 30-15–30-16
 calcium formate, 3-7
 calcium hydroxide, 1-22, 2-15, 2-24, 2-25, 2-26, 2-36, 5-27, 6-31, 6-33, 11-4
 efflorescence, and, 1-25
 calcium magnesium acetate, 35-17
 calcium monosulfoaluminate, 5-42
 calcium nitrate, 3-7
 calcium nitrite, 3-8, 3-9, 5-38, 11-5
 calcium oxide, 3-14, 26-3
 calcium silicate, 1-2, 1-3, 1-4, 1-6, 1-7, 1-12, 2-15, 2-25, 3-2, 5-12, 5-23
 calcium silicate glasses, 1-17
 calcium silicate hydrate, 1-6, 2-2, 2-25, 2-32, 2-37, 5-12, 5-35, 5-42, 6-31
 calcium silicocarbonate, 2-26
 calcium sulfate, 1-10, 2-6, 2-18
 calcium sulfoaluminate, 2-25, 3-14, 23-2

calcium thiosulfate, 3-7
 calcium-alumina-silicates, 6-33
 calcium–aluminate cement, 1-10
 Calgon®, 3-7, 14-2
 Caltrans' response spectra, 32-50–32-51
 camber, 4-32, 8-49, 9-18, 9-19, 9-20, 9-21, 10-23, 11-4, 11-23, 11-32, 11-33
 cameras, for cranes, 19-40
 canopy, for high-rise construction, 18-5
 cantilever, 9-7, 9-14, 9-19, 9-20, 9-22, 11-40–11-43, 12-43
 cantilever bridge construction, 29-4, 29-6, 29-9, 29-10, 29-11, 29-12, 29-13
 cantilever retaining wall, 14-48–14-50
 cantilever sheet piles, 14-52–14-53
 cantilever suspended spans, 11-36
 cantilever wall system, 16-20, 16-28
 cantilevered column system, 32-13
 capacity-reduction factors, 16-10
 capillary pores, 1-8
 capillary suction, 24-31, 24-32–24-33
 CAPO test, 21-15
 carbohydrate esters, 3-5, 6-8
 carbohydrates, 3-3
 carbon content of fly ash, 26-3
 carbon dioxide, 1-11, 1-22, 2-15, 2-17, 2-26, 2-27, 4-12, 5-10, 5-11, 11-58, 16-13, 26-1, 26-2
 carbon-fiber fabrics, 25-11
 carbon-fiber-reinforced cement-based composites, 22-14, 22-16, 22-20–22-24
 carbon-fiber-reinforced epoxy laminates, 25-9, 25-10
 carbon-fiber-reinforced polymer (CFRP), 22-21, 22-23, 22-24, 25-2, 25-3, 25-13
 carbon-fiber sheets, 11-60, 16-15, 22-24
 tow, 25-10–25-11
 carbon–glass–polyester composites, 22-21
 carbonates, 5-10, 6-7
 carbonation, 1-22, 1-25, 5-10–5-11, 5-29, 5-37, 11-58, 16-13, 17-1, 21-4, 21-54, 24-30, 27-22, 28-38, 30-24
 blast-furnace slag, and, 2-27
 fly ash, and, 2-15, 2-18
 shrinkage, 2-15, 4-10, 4-12
 silica fume, and, 2-32, 2-36
 carbonic acid esters, 3-12
 carboxylates, 3-5, 3-10
 carboxylic acid, 3-11
 carnauba wax, 30-18
 Casagrande's liquid limit device, 14-4, 14-5
 casing, 10-13–10-14
 casing beads, 15-18
 cast-in-place concrete, *see* concrete: cast-in-place

- mixing, 5-6–5-10, 6-39, 6-40, 11-6
- mixtures, design of, 6-1–6-43

- modified-density, 11-18
- no-fines, 1-15
- nondispersible, 15-10, 15-12–15-13
- nonshrink, 35-8
- normal-strength, 1-13, 5-1–5-44, 6-9–6-18, 6-19, 6-30, 36-5, 36-9
 - mixture proportioning for, 6-9–6-13
- normal weight, 5-32, 5-36, 6-2, 6-9, 6-13, 6-20, 8-26, 8-27, 8-29, 12-10, 31-8, 36-7
 - density of, 5-16
 - shrinkage in, 4-35
- no-slump, 6-5, 6-8, 20-2, 20-3, 20-20, 30-4
- placement, 5-6–5-10, 6-1–6-43, 8-9, 10-14, 10-17, 10-25, 10-27, 10-28, 11-6, 11-13, 11-26–11-27, 11-41, 12-8, 15-9, 19-4, 19-15, 19-45, 19-50, 23-10, 30-48–30-52
 - underwater, 15-6
- plastic, 2-11, 5-2, 15-21
- polymer-modified, 3-14–3-18, 6-8, 33-2, 33-10, 33-16
- post-tensioned, 10-25, 10-38, 10-39–10-40, 11-12
- precast 10-2, 10-38–10-39, 11-5, 11-42–11-43, 19-3, 19-4, 20-49, 20-51, 26-7, 30-60–30-67, 33-1–33-16, 34-1–34-24, 36-32
 - architectural, 30-4–30-73
- precast pretensioned, 11-25, 11-28, 11-29–11-33
- preplaced-aggregate, 15-2–15-6, 16-13
- prestressed, *see* prestressed concrete
- pretensioned, 10-25, 10-38–10-39, 10-40, 16-16
- prism test, 5-40, 8-30, 8-52, 28-35, 28-36–28-38
- pumping distance of, 19-15
- reactive powder, 5-2, 22-14, 22-16–22-17
- ready-mix, 19-14, 19-17
- recycled, 5-29
- reinforced, *see* reinforced concrete
- removal of, 23-6
- resistivity, 21-54–21-56
- roller-compacted, *see* roller-compacted concrete
- self-consolidating, *see* self-consolidating concrete
- shocked, 30-4
- shrink-mixed, 5-6
- silica fume, *see* silica fume
- site-cast, 10-28, 30-58, 33-3, 33-4, 33-5, 33-6, 33-8, 33-9, 33-10, 33-12, 33-14, 33-15, 33-16
- slurry-infiltrated fiber, 22-14–22-15
- stain, 29-26
- structural, 10-1–10-40, 11-17
- structural elements, 36-1–36-36
- super-high-strength, 22-16
- syrene–butadiene resin, 3-16, 3-17
- transporting, 5-6–5-10, 11-6

- truck-mixed, 5-6
- underwater, 3-13, 15-6–15-13
- unit weight of, 5-29, 11-17, 13-23, 26-7, 26-9, 26-10
- unreinforced
 - creep, 8-31–8-34
 - shrinkage, 8-29–8-31
- vacuum, *see* vacuum processing
- very high-strength, 6-18
- weight of, 15-9
- concrete–air interfaces, 21-44, 21-62
- concrete-to-concrete friction coefficient, 34-7
- condensed silica fume, 5-27
- condition assessment, 16-3, 16-4
- conduits, 12-8
- cone penetration test, 14-7, 14-13–14-14, 28-32
- cone snap ties, 30-38; *see also* ties: snap
- confined compressive strain, 25-19, 25-20
- confinement, compressive strength and, 36-9
- connectors, ASTM standards for, 28-5
- consolidated drained/undrained tests, 14-8–14-11
- consolidation, 5-2–5-6, 10-27, 11-6, 12-8, 12-22, 13-18, 13-22, 13-23, 13-26, 15-13, 15-20, 19-19, 23-10, 23-11, 23-16, 30-4, 30-16, 30-21
 - architectural concrete, 30-52–30-58
 - grout, 28-20–28-21
 - mobility slope, and, 21-36
 - settlement, 14-17, 14-18, 14-20, 14-22
 - test, one-dimensional, 14-17, 14-19
- constant rate of penetration test, 14-73
- constructability, 6-30, 6-40, 10-2–10-3, 16-11, 16-18, 19-4, 25-9, 29-19, 30-43, 33-3, 34-20
- construction joints, *see* joints: construction
- construction load, *see* load: construction
- construction load factor, 8-41–8-42
- Construction Robotics Management System (CREMS), 18-7
- construction tolerances, masonry, 28-26–28-27
- construction variations, 9-15
- construction, masonry, 28-15–28-27
- constructive solid geometry (CSG), 18-9–18-10
- contact surface materials, 7-6–7-8
- contact time, impact-echo testing, 21-34
- contaminants, in water, 15-4
- Context-Sensitive Design (CSD), 29-10–29-11
- continuous beams, 4-20
- continuous footings, 10-30
- continuous members, 9-7, 9-19
- continuous mixers, 20-59, 20-60, 20-62
- continuous multiple-span bending members, 7-35, 7-38, 7-44, 7-45
- contraction, 17-6, 17-10, 20-22, 20-54
 - thermal, 20-11, 23-14
- contraction joints, *see* joints: contraction
- control joints, *see* joints: control
- control tests, 5-33
- conveyors, 5-6, 11-6, 15-8, 19-45, 20-2, 20-10, 20-54, 20-61, 20-61–20-65, 20-68, 20-70, 30-51
 - belt speed of, 20-63
 - crawler-mounted, 20-62
 - wheel-mounted, 20-62
- coolants, 10-27
- corbels, 10-39, 36-18–36-21
- coring, 16-3, 16-4, 16-16, 16-22, 16-25, 20-38, 20-67, 27-5, 27-25
- corner reinforcement, 15-18
- correlation testing, 21-27–21-28
- corrosion, 1-21–1-22, 1-23, 3-7, 3-8, 4-32, 5-10, 5-11, 6-7, 11-5, 11-9, 11-18, 11-19, 11-33, 11-34, 11-55, 11-58, 12-3, 12-4, 12-22, 12-23, 12-27, 13-19, 15-2, 16-14, 16-2, 16-17, 16-18, 16-23, 16-24, 16-25, 16-29, 16-37, 16-38, 16-39, 16-40, 17-13, 22-23, 22-24, 23-16, 24-29, 24-30, 27-2, 27-5, 27-22, 27-23, 30-15, 35-8, 35-15, 36-4
 - assessment of, 16-25
 - blast-furnace slag, and, 2-27
 - calcium chloride, and, 5-31
 - carbonation, and, 2-15, 2-27
 - chloride-induced, 16-20, 16-23
 - evaluation of, 21-52–21-60
 - fly ash, and, 2-17–2-18
 - inhibitors, 1-22, 3-8, 3-9, 5-38, 5-39, 11-5, 11-58, 11-59, 11-60, 12-4, 12-5, 16-16, 16-18
 - categories of, 3-9
 - setting times, and, 3-9
 - overlays, and, 23-3, 23-5
- pavement, 11-58
- pier, 27-23
- pile, 11-46
- potential, 21-53
- protection, 5-37–5-39, 11-2, 11-10, 11-12, 11-19, 11-23–11-24, 11-38, 11-60, 12-2, 12-4, 12-9, 12-31, 16-14, 16-15, 16-18, 16-19
- rate testing, 21-60
- reinforcing bar, 13-20
- reinforcing steel, *see* reinforcing steel: corrosion of resistance, 5-29
 - steel-reinforced engineered cementitious composite (R/ECC), 24-33–24-36
- seasonal variation in, 21-59
- steel reinforcement, 16-1, 16-2, 16-14, 16-20
 - rate of, 16-3, 24-34

 20-17, 20-20, 20-22, 20-34-20-37, 20-38,
 20-40, 20-41-20-42, 20-45, 20-47, 20-51,
 20-66, 20-67, 20-68, 20-69
 seepage, 20-41, 20-42, 20-49
 lift-off test, 12-21
 lift-slab construction, 10-28, 10-30-10-33, 11-29,
 11-33, 12-41
 lifting capacity, crane, 19-32, 19-33, 19-36, 19-38,
 19-40, 19-43
 lifting collars, 10-32, 10-33
 lifting height, crane, 19-32, 19-33
 lifting hook, crane, 19-6, 19-21, 19-33, 19-40
 lifting inserts, 11-50
 lifting jacks, 10-31, 10-32, 10-33, 10-34
 lifting lugs, 10-39
 lifting moment, 19-33
 lifting points, 11-51
 lifts, 19-1, 19-47-19-48, 29-26, 30-52, 30-53, 30-54,
 30-57
 grout, 28-3, 28-20, 28-33
 passenger, 19-4
 roller-compacted concrete, 20-8, 20-10, 20-14,
 20-17, 20-18, 20-21, 20-34, 20-38, 20-40,
 20-43-20-47, 20-51-20-53, 20-55, 20-57,
 20-58, 20-62, 20-64-20-70
 scissor-type, 19-2, 19-47
 thickness of, 20-67
 lighting, bridge, 29-29
 lightweight-aggregate concrete factor, 36-28
 lignin, 3-2, 3-11
 lignite, 2-2, 2-4, 2-6, 2-11, 2-17
 lignosulfonates, 3-3, 3-7, 6-8
 lime, 1-10, 2-11, 2-23, 2-32, 2-36, 2-39, 5-23, 6-8,
 28-6, 28-8, 28-10
 limestone, 1-2, 1-3, 1-19, 5-17, 5-21, 11-4, 20-25,
 30-14, 30-26
 limit-state analysis, 32-57-32-58

- limit states, 16-2–16-3, 16-27, 34-2, 34-3, 34-10
 - shear stress, 34-21
 - strain, 36-10
 - strength, mechanism approach to, 34-2, 34-3
- limonite, 1-19, 6-4
- line pump, 19-17
- linear hyperbolic function, 21-21, 21-22, 21-23
- linear kinetics, 21-21
- linear polarization, 21-56–21-60
- linear variable differential transformers (LVDTs), 27-17, 27-18, 27-25, 27-28
- linearity, of an instrument, 27-15
- liners, 20-38, 30-27–30-30, 30-32, 30-34, 30-55
 - elastomeric, 30-18–30-19, 30-28–30-29, 30-40
 - landfill, 14-26–14-27
 - metal, 30-30
 - plastic, 7-7, 30-18, 30-21, 30-28, 30-29
 - polystyrene foam, 30-29–30-30
 - polyurethane, 30-29
 - polyvinyl chloride, 30-29
 - rubber, 30-18–30-19, 30-28
 - wood, 30-28
- lintels, fire resistance of, 31-14
- liquefied natural gas (LNG), 11-3, 11-55, 13-5–13-6, 13-13, 13-14, 13-27
- liquefied petroleum gas (LPG), 13-13
- liquid-containing structures, 10-23–10-26, 16-2; *see also* liquid-retaining structures, tanks
- liquid head, 7-24
- liquid limit, 14-4–14-5, 20-12
- liquid nitrogen, 11-5, 11-55
- liquid-retaining structures, 4-34, 14-23, 17-2, 17-6, 17-7, 17-8; *see also* liquid-containing structures, tanks
- lithium compounds, 3-18
- live end, 16-16
- live load, 4-21, 7-2, 7-8, 7-10, 7-14, 7-23, 7-24, 7-38, 8-6, 8-9, 8-34, 8-41, 8-42, 8-43, 8-47, 9-7, 9-12, 10-9, 10-16, 10-20, 10-31, 10-34, 11-18, 11-36, 11-41, 24-37, 25-8, 25-9, 25-13, 27-3, 28-41, 32-12, 32-22, 32-27, 32-28, 33-10, 34-2, 34-3, 34-9, 34-10, 34-21, 36-4
 - deflection, 9-17, 9-18, 9-20
 - demolition, and, 12-39
 - design, 10-5, 27-28
 - vs. service, 9-12
 - gravity, 10-5
 - lateral, 10-5–10-7
 - factor, 10-4, 12-39
 - moments, 9-13
 - permanent, 9-12
 - repeated cycles of, 8-51
 - roof, 27-3
- load, 4-4, 4-5, 4-6, 4-7, 7-3, 7-8, 7-9, 7-12, 7-13, 7-14, 7-15, 7-16, 7-17, 7-18, 7-21, 7-22, 7-23–7-27, 7-35–7-36, 9-12, 10-3–10-7, 10-39; *see also* loading
 - accidental, offshore structure, 13-25
 - axial, 10-11, 28-27, 28-52, 28-53, 28-55, 28-58, 28-59, 28-60, 28-62, 28-63, 28-65, 28-66, 28-68, 32-36, 36-5–36-7, 36-10, 36-24
 - axial compressive, 28-52
 - bending, 24-6, 32-36
 - buckling, 10-16, 28-52
 - column, 10-11
 - compression, 7-16
 - compressive, 4-5, 34-10
 - construction, 8-1–8-19, 9-13, 9-19, 10-10, 10-33

- Marsh cone flow test, 24-11
- masonry, 9-22, 28-1–28-68
 - admixtures, 28-14–28-15
 - bond patterns, 28-16–28-18
 - bracing of, 28-22
 - buildings, seismic-force-resisting, 32-34–32-38
 - cement mortar, 28-9
 - clay, 31-7
 - cleaning of, 28-25
 - codes and standards, 28-2
 - compressive strength, 28-35–28-38, 28-50, 28-53, 28-62, 28-64, 28-65, 28-66, 28-68
 - construction, 28-15–28-27
 - environmental factors, 28-22–28-25
 - tolerances, 28-26–28-27
 - cracking, 28-38
 - detailing, 28-38–28-39
 - equivalent thickness of, 31-7, 31-11
 - grout, 28-3, 28-4, 28-5, 28-9–28-11, 28-14, 28-16, 28-19–28-22
 - inspection, 28-27–28-38
 - lateral support of, 28-48, 28-49
 - lintels, fire resistance of, 31-14
 - materials, 28-4–28-15
 - modular layout of, 28-16–28-18
 - moisture migration, 28-38–28-39
 - painting of, 35-16
 - partially grouted, 28-55, 28-56, 28-64, 28-65, 28-66
 - plain, 28-4
 - project specifications, 28-39–28-40
 - quality assurance levels, 28-29–28-31
 - reinforced, 28-4, 28-13, 28-24, 28-41, 28-42, 28-43–28-45, 28-54–28-58, 28-59, 28-60, 28-63–28-68
 - sample panels, 28-25
 - shear walls, 32-34–32-38
 - approximate period of, 32-24
 - seismic detailing of, 28-43–28-45, 32-35–32-38
 - structural design, 28-40–28-68
 - testing, 28-27–28-38
 - unreinforced, 28-4, 28-13, 28-41, 28-42, 28-43–28-44, 28-51–28-54, 28-59, 28-60, 28-61–28-63
 - walls, fire-resistance rating of, 31-6–31-7
- masonry units, 28-59, 31-14
 - clay, 28-11–28-13
 - concrete, 28-11
 - defined, 28-3
 - equivalent thickness of, 31-7
 - hollow, 28-3, 28-11, 28-13, 28-18, 28-37, 28-39, 28-45, 28-47, 31-7
 - solid, 28-3, 31-7
 - testing, 28-35
- mass, 32-49, 32-50
 - defined, 32-48
- mass concrete, 10-26–10-27, 15-22–15-23, 20-3, 20-11, 20-34, 20-38, 20-40, 20-42, 20-53, 20-64, 30-59
 - cracking analysis of, 20-31
 - materials for, 10-26–10-27
 - mixture design of, 10-27
 - quality control, 10-27
 - Soniscopes testing of, 21-6
- mast-climbing passenger hoist, 19-47
- masts, crane, 19-4, 19-8, 19-9, 19-19, 19-22, 19-24, 19-25, 19-26, 19-28, 19-29, 19-40
 - types of, 19-29
- mat
 - blasting, 11-61
 - timber, 11-32
 - vacuum, 15-14
- mat footings, 14-37–14-43
 - bearing capacity of, 14-37–14-40
 - flexible, design of, 14-40–14-43
- mat foundations, 10-12, 15-23
- match casting, 11-38, 11-39, 11-42
- material allowances, 12-10
- material handlers, 19-1, 19-45–19-47
- material weights, 10-5
- maturity, 8-25, 8-26, 21-17, 21-24
 - degree-hr, 20-69
- maturity index, 21-18, 21-23, 21-24
- maturity, lift-joint, 20-34, 20-36
- maturity meters, 21-26
- maturity method for estimating strength, 21-16–21-25
- maturity rule, 21-17
- maximum considered earthquake (MCE), 32-7, 32-8, 32-23
- maximum distributed pressure, 7-43
- maximum practical achievable density (MPAD), 20-21
- mechanical gauges, 27-13, 27-14, 27-16–27-17
- mechanically stabilized earth, 14-56
- mechanized form systems, 19-48–19-50
- medians, bridge construction within, 29-15
- melamine formaldehyde, 6-8
- member size
 - creep, and, 8-33
 - shrinkage and, 8-30
- membrane
 - curing, 11-6, 30-59
 - curing compounds, 11-50
 - electrometric, 35-15

- PVC, 20-49, 20-51
 - sealing compounds, 11-5
 - traffic-bearing, 35-15
 - upstream, 20-38, 20-40, 20-42, 20-44
 - waterproof, 33-2
- mesopores, 1-8
- metakaolin, 11-4, 26-2
- metakaolin, highly reactive, 2-38–2-42
 - composition of, 2-38

 - transfer, 10-23, 10-33, 27-26, 34-5, 34-8
 - unbalanced, 10-21
 - vertical, 16-34, 16-35, 16-36, 16-37
- monostrand tendons, *see* tendons: unbonded monostrand
- mooring, 13-2, 13-9, 13-11, 13-13, 13-14, 13-25, 13-28, 13-30
- mortar, 2-10, 2-24, 2-27, 2-36, 3-12, 3-15, 5-43, 6-7, 6-8, 6-18, 6-31, 11-12, 11-18, 11-20, 11-49, 11-50, 11-54, 11-60, 15-13, 16-13, 20-18, 20-56, 21-12, 21-16, 21-18, 21-21, 21-23, 23-13, 24-2, 24-6, 24-11, 24-31, 24-35, 28-2, 28-3, 28-4, 28-5–28-9, 28-10, 28-18–28-19, 28-36, 28-49, 28-59, 30-22, 30-30, 30-32, 30-68, 31-14
 - activation energy of, 21-18
 - aggregate ratio test, 28-33
 - ASTM standards for, 28-5
 - bars, expansion of, 2-27
 - bedded area, 28-3
 - cement–lime, 28-6
 - compressive strength, 28-6, 28-8, 28-9, 28-23, 28-32, 28-33
 - cubes, 6-31, 20-20
 - epoxy, 33-10
 - field-prepared, 28-6–28-8, 28-32, 28-33
 - for overlays, 23-10, 23-11
 - freezing of, 28-23
 - high-early-strength, 33-16
 - joints, 28-9, 28-19, 28-26, 28-37, 30-30
 - tolerances, 28-26
 - laboratory-prepared, 28-6–28-8, 28-32
 - Portland cement, 28-6, 28-8, 28-9, 30-68
 - reinforced, 24-31, 24-32, 24-35, 24-36, 24-37
 - sand–lime, 28-6

- selecting, 28-8–28-9
- stains, 30-71
- testing of, 28-32–28-33
- volume/stone volume ratio, 6-18
- Mo-Sai process, 30-4
- motion attenuation, 32-3
- motor-in-head vibrators, 30-53
- moving-counterweight system, for cranes, 19-26
- mudsills, 7-3, 7-16, 7-35
- Mueller–Breslau principle, 10-16
- mullite, 2-6
- multi-bay model, 8-13, 8-14, 8-15, 8-16, 8-39, 8-40
- multiple fine cracking fiber-reinforced cementitious composite, 24-4
- multi-stemmed beam, 33-4
- muratic acid, 30-71
- mushrooming, 6-40

N

- nanopores, 26-2
- naphthalene formaldehyde, 6-8
- Natchez Trace Parkway Arches, 29-2
- native materials, use of for bridge construction, 29-26–29-28
- natural period, 32-48, 32-51
- near-surface-mounted (NSM) strengthening rods, 25-3
- negative moment, 10-8, 10-16, 10-17, 10-18, 10-21, 11-36, 11-38, 11-40, 11-50, 12-11, 16-34, 16-36, 16-37, 18-11, 22-17, 31-6, 36-14
- neoprene bearing pads, 11-23, 11-32, 11-36, 11-54, 30-47, 30-64
- net area, 28-3
- neural network analysis, 21-35
- Newton's second law, 32-48
- nitrogen injection, 5-32
- No. 4 sieve, 1-14, 1-15, 6-4, 20-11, 30-17
- No. 8 sieve, 1-15, 30-17
- No. 16 sieve, 1-15
- No. 30 sieve, 1-15
- No. 50 sieve, 1-15, 30-17, 30-21
- No. 100 sieve, 1-14, 1-15, 5-43, 6-4, 14-2, 30-14, 30-17
- No. 200 sieve, 20-23, 20-58
- nodal zone, 36-16, 36-18, 36-21
- nodes, 36-15, 36-16
- no-fines concrete, 1-15
- noise error, 27-16, 27-18, 27-19
- nominal dimension, masonry unit, 28-3
- nominal maximum size aggregate (NMSA), 15-4, 20-60, 20-61
- nominal moment strength, 22-12, 36-24

- nominal shear strength, 36-14
- nondestructive testing, 11-32, 16-3, 16-4, 16-20, 16-24, 16-38, 16-39, 16-40, 21-1–21-63, 27-2, 27-5, 27-6–27-9
 - condition assessment, 21-28–21-62
 - flaw detection, 21-28–21-62
 - modal, 27-7
 - to estimate in-place strength, 21-2, 21-2–21-28
 - to evaluate integrity, 21-2
- nondispersible concrete, 15-10
 - horizontal flow time of, 15-12–15-13
- non-engineered design, 28-41
- nonprismatic members, 9-14
- nonsway frames, 10-15
- Norhordland Bridge, 13-14
- normal-strength concrete, *see* concrete:
 - normal-strength
- no-slump concrete, 20-2, 20-3, 20-20
- nuclear power reactors, 11-55
- nuclear reactors, 11-24
- nuclear test methods, 21-60–21-62
- Nurse–Saul maturity function, 21-17, 21-18
- nylon fibers, 22-19

O

- Objective MicroStation, 18-12, 18-13
- object-oriented CAD, 18-12
- occupancy category, 32-8–32-9, 32-11
- occupancy, changes in, 8-49
- Occupational Safety and Health Administration
 - formwork standards, 7-19–7-21
- ocean spray, 5-38
- octyl alcohol, 3-12
- Odyssey™, 18-5–18-6
- offshore structures, 11-3, 11-15, 11-17, 11-18, 11-56, 13-1–13-31, 14-50
 - construction of on barges, 13-29
 - cost of, 13-31
 - service life of, 13-19
 - steel, removal of, 13-17
 - surface of, 13-23
- oil-storage facilities, 13-13
- oil-storage tanks, subsea, 13-15
- omega strain gauge, 27-19
- one-way joist construction, 7-9
- onshore concrete structures, 13-1, 13-2, 13-3, 13-6, 13-25
 - precast, 13-26
- on-site precasting, 10-28–10-30
- onyx, 30-32
- opal, 5-40
- opaline cherts, 5-28

operator cab, crane, 19-25, 19-29, 19-36, 19-37, 19-39

optical fiber strain gauges, 27-21

ordinary least squares, 21-25

ordinary moment-resisting frames (OMRFs), 32-13

O-ring gasket, 11-39, 11-40

oscillographs, 21-45

out-of-plumb tolerances, 28-26

outriggers, 11-32, 11-35, 19-17, 19-29, 19-32, 19-36, 19-37, 19-38, 19-46

oven-dry aggregates, 1-16, 5-30, 20-17, 20-20

overburden pressure, 14-11, 14-12, 14-14, 14-16, 14-21, 14-22

overcompression, 11-34

overconsolidation ratio, 14-60

overdesign, 6-13, 6-38, 20-42–20-43

overlays, 23-1–23-16

- aggregates used in, 23-3
- bonded concrete, 23-1–23-16, 33-2, 33-16
- bond strength of, 23-4–23-13
- compressive strength of, 23-3
- cost of, 23-15
- delamination of, 23-2, 23-4, 23-12, 23-13, 23-14
- joints, and, 23-12–23-13
- material properties of, 23-2–23-4
- mixture proportions of, 23-2–23-3
- permeability of, 23-3–23-4, 23-14
- protection characteristics of, 23-14
- rapid construction of, 23-15
- service life of, 23-16
- shrinkage of, 23-4
- surface characteristics of, 23-14
- surface preparation for, 23-6–23-10
- test patches of, 23-8
- thickness of, 23-4, 23-13

over-reinforced beams, 25-4, 25-5, 25-8

overstrength factor, 32-13, 32-20, 32-27, 32-28, 34-8, 34-10, 34-21

overstress, 10-14, 11-36, 12-27, 16-35, 16-36, 16-37

overvibration, 30-56, 30-57

oxide film, 5-11, 5-37

- on steel, 1-22, 2-17

oxides, 1-3, 1-4

oxidization, 12-29

P

pachometer, 16-18

pads

- neoprene bearing, 11-23, 11-32, 11-36, 11-54, 30-47, 30-64
- vacuum, 15-14

pan joist, 7-9

panel forms, 7-11–7-12

panel thickness, 10-30

pans, 7-9

paper, waterproof, 15-18

parabolic hyperbolic model, 21-21, 21-22

parallel strand lumber (PSL), 7-35

parallel structural system, 32-52

parallel-to-grain loading, 7-28

parapets, 20-45

- precast concrete, 33-2, 33-3, 33-12

parking structures, 1-25, 4-25, 4-30, 5-10, 5-38, 9-9, 10-19, 10-23, 11-33, 11-58, 12-4, 12-31, 16-2, 16-11, 16-16, 23-1, 32-43, 35-3, 35-5, 35-16

particle grading, 1-14, 1-15–1-16, 5-30, 5-32, 20-11

particle-size distribution, 1-14, 1-15, 2-5, 2-32, 14-3, 26-3

partition, 9-22

- load, 32-22

passenger hoists/lifts, 19-4, 19-47

passivation, 2-18

passive–active corrosion inhibitors, 3-9

passive corrosion inhibitors, 3-9

passive vs. active failure mechanism, 14-44

paste, 1-6, 1-7, 1-8, 1-9, 1-13, 1-14, 1-15, 1-23, 2-10, 2-14, 2-15, 2-20, 2-21, 2-23, 2-24, 2-25, 2-26, 2-27, 2-30, 2-33, 2-34, 2-36, 2-37, 3-3, 3-4, 3-6, 3-10, 3-13, 3-14, 3-16, 4-7, 4-8, 4-11, 4-12, 5-2, 5-10, 5-16, 5-30, 5-34, 5-35, 5-40, 5-42, 10-3, 10-25, 11-50, 12-6, 15-14, 15-20, 20-35, 20-47, 20-48, 20-51, 20-58, 20-62, 20-68, 20-69, 21-55, 22-15, 22-16, 24-2, 27-22, 28-25, 30-14, 30-20, 30-24, 30-25

- color, 30-12
- defined, 20-71
- geopolymer, 26-3, 26-5
- permeability, 5-10, 5-11
- roller-compacted concrete, 20-2, 20-14, 20-18, 20-20

paste–aggregate interface, 21-31

paste/aggregate ratio, 6-18

patching, 11-59, 12-20

pavement, 17-14–17-15, 20-1, 22-3

- bonded overlays for, 23-15
- flaw detection in, 21-36
- measuring thickness of, 21-47
- overlay mixtures on, 23-3
- prestressed concrete, 11-58
- stiffness, 23-15

paving lanes, 20-66

PCI Plant Certification, 30-10

P-delta effect, 10-15, 10-16, 10-30, 28-67, 32-20, 32-26, 32-27, 32-56, 36-25

pea gravel, 11-23, 28-10, 31-7

- peak ground acceleration, 32-2, 32-3, 32-4, 32-5, 32-51
 - ratios, 32-6
- peak ground displacement, 32-2, 32-5
- peak ground velocity, 32-2, 32-5
- peak plotting, 21-46
- pedestrian walkways, 29-25, 29-26
- pelletization, 2-19, 2-22
- penetration blow count, 14-37
- penetration resistance, soil, 14-11
- penetrations, in beams or drop caps, 12-8
- Penobscot Narrows Bridge and Observatory, 29-14–29-15
- percussion tools, hand-held, 12-40
- performance evaluation, 27-1–27-31
 - bridges, 27-21–27-31
 - pretest planning, 27-4–27-6
- performance specifications, 30-9
- period, 10-6
 - defined, 32-48
 - natural, 32-48, 32-51
- perlite, 1-17, 6-2, 15-17, 31-8
- permanent forms, 7-7, 30-4
- permeability, 2-15, 2-24, 2-25, 3-2, 3-7, 3-15, 5-2, 5-10, 5-29, 5-35, 5-38, 5-39, 6-8, 10-23, 11-5, 11-7, 12-22, 13-22, 14-29, 16-12, 24-31
 - blast-furnace slag, and, 2-24
 - clay liner, 14-26
 - coefficient, 14-24, 14-26, 14-27
 - defined, 20-71
 - fly ash, and, 2-14

 23-16, 30-12
 engineered cementitious composite (ECC),
 24-8–24-12
 geopolymer concrete, 26-3–26-4
 procedure for, 6-22–6-23
 public exposure, seawall panel, 16-38
 pugmill mixers, 20-59, 20-60, 20-62, 20-63, 20-71
 pull-off test, 21-26
 pullout, 1-21, 11-14, 11-32, 11-42, 24-7
 fiber, 22-5, 22-6, 22-13, 24-7, 24-26
 resistance, 22-9
 strength, 8-26, 21-11, 21-12, 21-24
 test, 21-3, 21-10–21-15, 21-26, 24-27
 cast-in-place, 21-10, 21-13
 coefficient of variation for, 21-12
 failure mechanism of, 21-12, 21-13
 post-installed, 21-13–21-15
 pulse-echo testing, 16-25, 21-31
 pulse velocity, 21-5–21-8, 21-27, 27-7
 pumice, 1-17, 31-7
 pumpability, 13-23
 pump-and-boom combination, 19-15–19-17
 pump-delivery system, 10-27
 pumps, 5-6, 11-6, 12-8, 13-26, 15-7, 15-8, 15-13,
 19-1, 19-2, 19-3, 19-4, 19-6, 19-9,
 19-15–19-19, 30-21, 30-32, 30-51–30-52
 boom, 19-17
 line, 19-17
 stationary, 19-9, 19-17
 trailer, 19-17
 truck-mounted, 19-17
 vacuum, 15-15
 vs. belt conveyors, 19-45
 with pipelines, 19-17–19-19

punch diameter, 8-27
 punching shear, 8-12, 8-27, 8-37, 8-38, 8-40, 8-43,
 10-22, 10-23, 11-8, 11-14, 27-25, 27-29
 failure, 8-27, 8-37, 8-38, 27-25, 27-29
 strength, 8-27, 8-37, 8-38, 8-40, 8-43
 stresses, 8-43, 8-46, 8-47
 test, 21-3
 two-way, 10-12
 PUNDIT, 21-8
 purlins, 8-53
 pushover analysis, 32-58
 P-waves, 16-4–16-7, 21-31, 21-32, 21-33, 21-34,
 21-35
 pylons, 29-13, 29-14, 29-15, 29-26

Q

quality assurance
 architectural concrete, 30-9–30-10
 defined, 30-73
 masonry, 28-29–28-31, 28-35
 quality control
 architectural concrete, 30-9–30-10
 defined, 30-73
 quartz, 1-2, 2-6, 2-29, 2-38, 5-21, 5-40, 6-9, 22-16,
 30-14, 30-26, 30-32
 quartzite, 1-19
 quasi-static load testing, 27-9–27-13, 27-17, 27-20
 quays, floating, 13-14
 quick load test, 14-73

R

R/ECC, *see* steel-reinforced engineered cementitious
 composites
 radar, ground-penetrating, 21-42–21-48, 21-63
 radiation shielding, 1-19, 5-17, 6-4
 radioactive test methods, 21-60–21-62
 radiography, 21-60, 21-61–21-62, 27-5
 radiometry, 21-60–21-61
 raft foundation, 10-12
 railroad ties, 11-55–11-56
 rain, 5-15, 7-43, 8-48, 11-20, 11-21, 11-33, 11-40,

- silty, 14-5
- ultimate bearing capacity in, 14-31
- weight of, 6-12, 6-25, 6-26
- sand/binder ratio, 24-9
- sandblasting, 30-4, 30-6, 30-9, 30-12, 30-13, 30-16, 30-17, 30-20, 30-22–30-24, 30-27, 30-28, 30-30, 30-32, 30-34, 30-35, 30-36, 30-40, 30-44, 30-46, 30-47, 30-59, 30-68, 30-71
- sandstone, 1-19
- saturated surface dry aggregates, 1-16, 5-30, 20-19, 20-69, 26-8
- saturation, 5-10
 - of soils, 14-7, 14-20, 14-69
- saws, 17-5
- scaffolding, 7-14, 7-19, 8-9, 10-34, 10-36, 11-21–11-23, 12-6
- Scaffolding, Shoring, and Forming Institute guides, 7-22
- scaling, 5-31, 5-34, 5-35, 15-22, 16-14, 22-14, 30-25, 30-26
 - resistance, 2-15, 2-37, 2-39, 3-7, 3-8, 3-12, 5-29, 5-34–5-35
- scarification, 23-6
- schists, 1-19
- Schokbeton, 30-4
- scoria, 1-17, 31-7
- scrapers, 20-64–20-65
- scratch coat, plaster, 15-19
- screeds, 15-18, 18-2–18-3, 23-10, 23-14, 23-15
- screw jack, 10-34, 11-32
- sea salts, 13-21
- sealants/sealers, 5-35, 17-8, 30-17, 30-18, 30-28, 35-15
 - acrylic, 30-69–30-70
 - joint, 17-13, 30-67
 - precast concrete, 30-67
 - silane, 23-14, 35-15
 - surface, 5-38, 5-39
 - wood, 30-17, 30-18, 30-28
- seat extensions, 32-61
- seawalls, 13-9, 14-50
 - repair of, 16-20–16-40
- seawater, 1-22, 1-25, 2-14, 2-17, 2-18, 2-24, 3-7, 5-10, 5-29, 5-37, 5-38, 11-9, 11-58, 11-59, 13-2, 13-19, 13-20, 13-22, 13-25, 16-20, 16-26
 - blocking inflow of, 11-59
 - galvanizing, and, 11-10
 - resistance to, 2-25–2-26
- secant modulus, 8-28
- second-generation superplasticizers, 3-5
- section modulus, 7-39, 7-40, 7-41, 9-3
 - beam, 10-10
 - composite member, 10-10
- sectional tower crane, 19-24, 19-29
- seepage, 14-10
 - groundwater, 14-23–14-24, 14-25
 - joint, 20-40, 20-41
 - lift-joint, 20-42, 20-49
 - roller-compacted concrete, 20-7, 20-38–20-40
- segmental concrete construction, 33-9
- segregation, 5-2, 5-6, 5-31, 5-43, 6-40, 10-3, 10-27, 15-2, 15-18, 15-20, 15-25, 20-11, 20-14, 20-23, 20-34, 20-61, 20-63, 20-65, 20-66, 27-5, 30-21, 30-51, 30-52
- seismic
 - activity/events, 7-27, 10-14, 10-30, 11-17, 16-24, 16-27, 20-46
 - base shear, 32-22–32-24
 - bracing systems, 34-1–34-24
 - hybrid system of, 34-11, 34-12, 34-15, 34-17, 34-20, 34-22
 - strength criterion for, 34-2–34-4
 - design, bridges, 32-48–32-56
 - design categories, 32-7, 32-11–32-21, 32-29
 - detailing, masonry, 28-41–28-45
 - detailing, prescriptive, 28-41–28-45
 - detailing, shear walls, 28-43–28-45, 32-35–32-38
 - echo method, 21-33
 - effects, analysis of, 32-19–32-20
 - force, 32-12, 32-13, 32-20, 32-21, 32-26, 32-27, 32-28, 32-29, 32-34, 32-43, 32-44, 32-45, 32-46, 32-48
 - design, code-specified, 32-12, 32-13, 32-28
 - horizontal, 32-27
 - resisting piles, 32-56
 - resisting system, 32-12, 32-13, 32-20, 32-21, 32-29–32-34
 - vertical distribution of, 32-24
 - joints, 17-9–17-10
 - load, *see* load: seismic
 - moment-resisting frame systems, 34-7–34-18
 - regions, 11-54, 36-9
 - resistance, 16-22, 16-23, 24-39, 32-1–32-61
 - columns, 32-53
 - response history, 32-19
 - retrofit, 32-42–32-46, 32-56–32-61
 - footings, 32-45
 - risk evaluation, 32-6
 - wave, 17-10
 - weight, effective, 32-22
 - zones, 22-24

- self-consolidating concrete, 3-6, 3-14, 5-2, 5-43, 6-35, 7-26, 11-6, 11-54, 15-19–15-22, 30-16
 - applications, 15-22
 - mix design, 15-20
 - testing methods, 15-20–15-22
- self-consolidating grout, 28-10–28-11
- self-erecting cranes, 19-22
- self-propelled mobile mixer, 19-15
- semirigid modeling, 32-18
- sensitivity, of an instrument, 27-15
- sensors, embedded, 16-20
- series conveyor, 19-45
- series structural system, 32-52
- service crane, 19-43
- service load, *see* load: service
- service moments, 9-3–9-4, 9-12, 25-7
- service torsional moment, 9-8
- serviceability, 4-18–4-34, 12-23, 12-28, 12-29, 12-31, 16-2, 16-3, 16-8, 27-4, 35-14, 35-15, 36-3, 36-27
 - corrosion, and, 16-2
 - failures, 8-20
 - limit state, 16-2, 16-27
- servohydraulic cylinders, 27-10–27-13
- setting, 10-23, 10-26; *see also* setting time
 - rapid, 8-21
 - rate, 5-31, 5-32
- setting time, 3-3, 5-12, 5-33, 6-7, 6-8, 6-34, 7-26; *see also* retarders
 - admixtures, and, 5-28
 - antiwashout admixtures, and, 3-14, 15-11, 15-13
 - calcium chlorides, and, 3-7
 - corrosion inhibitors, and, 3-9
 - maturity method, and, 21-24
 - Portland cement, 2-9–2-10
 - silica fume, 2-34
 - slags, and, 2-20
- settlement, 10-14, 10-17, 11-32, 14-14–14-23, 17-10, 20-44, 28-38
 - consolidation, 14-17, 14-22, 14-62, 14-68, 14-69
 - cracks, 30-56
 - differential, 14-23, 17-6, 30-36
 - elastic, 14-74
 - immediate, 14-21–14-22, 14-68, 14-69
 - in clay, 14-32
 - in granular soils, 14-15–14-16
 - in saturated clays, 14-16–14-23
 - mat footing, 14-40
 - maximum allowable, 14-22, 14-23
 - pile, calculation of, 14-62–14-63
 - pile group, 14-65–14-69
 - secondary, 14-14
- shadowing, 30-21
- shadows, on bridges, 29-22–29-23
- shale, 1-14, 1-17, 1-19, 5-28, 5-30, 6-4, 20-11, 31-7, 31-8
 - ASTM standards for, 28-4–28-5
- shape, aggregate, 1-14, 1-15, 5-30, 6-7, 6-36, 6-37, 20-11, 21-16
- she bolts, 7-11, 30-39
- shear, 3-14, 7-30, 8-27, 8-41, 8-47, 10-7, 10-8, 10-11, 10-15, 10-16, 10-17, 10-24, 10-33, 10-37, 10-38, 11-15, 11-18, 11-32, 11-36, 11-57, 12-38, 13-24, 14-5, 16-34, 17-2, 20-43, 25-11, 28-58, 28-63, 28-67–28-68, 32-23, 32-38, 32-56, 36-10
 - base, 32-22–32-24, 32-27, 32-29, 32-62
 - beam–column joint, 34-17, 34-20
 - bond-reduction coefficient, 25-16
 - capacity, 25-4, 25-6, 25-7, 25-9, 25-12, 25-16–25-18, 32-26, 32-43
 - allowable, 10-22
 - nominal, 34-9
 - coefficient, 10-16
 - column, 34-21
 - connectors, 10-8, 10-9
 - cracks, 36-14
 - deflection, 7-34
 - demand, 32-26
 - distribution, 32-30
 - engineered cementitious composite (ECC), 24-14–24-15
 - failure, 8-47, 10-22, 27-4
 - flexural, 36-34
 - flow, 10-8
 - footings, and, 10-12
 - force, 10-9, 10-16, 10-33, 14-39, 18-10, 18-11, 28-51, 28-54, 28-58, 28-61, 28-63, 32-34, 32-35, 32-40, 32-43, 36-34
 - column, 34-17
 - maximum, 7-36, 7-39, 7-40, 7-41, 7-43, 7-44, 7-45, 7-46, 8-12, 14-50
 - modulus of rupture, and, 8-27
 - radial, 11-4
 - total, 8-16
 - friction, 13-22, 22-18, 34-6, 36-10
 - interlock, 22-9
 - heads, 10-22, 10-32
 - horizontal, 10-7, 10-8, 11-36, 11-41, 32-34, 32-35, 36-25
 - distribution of, 32-27
 - horizontal torsional moments, and, 32-25
 - joint, 32-54
 - keys, 11-38, 11-44, 11-54, 27-27–27-28
 - lag, 11-43
 - lateral, 32-34

- load, 10-8, 24-6, 28-50, 28-60, 34-8, 36-15
- mixers, 11-6
- modulus, 21-39
- moment, 14-50, 32-29–32-30
- nominal, 36-10
- perimeter, 8-27, 10-22
- plywood, 7-38
- prestressed elements, 36-34–36-35
- punching, *see* punching shear
- reinforcement, 10-32, 11-30, 24-21, 25-4, 25-6–25-7, 26-16, 28-58, 28-67, 28-68, 32-38, 32-54, 34-10, 36-35
- rolling, 7-28
- solid rectangular beam, 7-36
- story, 32-25, 32-26, 32-27, 32-29, 34-19
- strength, 5-15, 8-20, 8-41, 10-22, 11-17, 13-22, 20-34–20-37, 22-13, 22-24, 28-50, 28-61, 28-68, 36-14–36-15, 36-36
 - foundation soil, 14-7, 14-11
 - nominal, 36-14
 - pullout strength, and, 21-12
 - roller-compacted concrete, 20-34–20-37
- stress, *see* stress: shear
- torsional, 32-34
- transfer, 10-10, 10-19, 10-21, 11-18, 11-41, 32-34, 32-38, 32-40, 33-4, 33-10, 34-6, 34-8, 34-9, 34-10, 35-11
- upward, 14-39
- vertical, 10-21, 11-36
- walls, 10-6, 10-14, 10-15, 10-16, 10-34, 12-38, 15-23, 28-42, 28-58, 28-64, 30-5, 30-45, 32-12, 32-13, 32-29, 32-30, 32-31, 32-34, 32-34–32-42, 32-43, 32-45, 35-11
 - approximate period of, 32-24
 - calculating number of bays for, 32-21
 - defined, 32-62
 - deflection of, 10-6
 - discontinuous, 32-19
 - empirical design of, 28-46–28-49
 - foundation analysis/design, 32-38–32-40
 - seismic detailing requirements for, 28-43–28-45
- yield stress, 15-21
- shear span/depth ratio, 22-13
- sheathing, 7-6–7-8, 7-10, 7-11, 7-34, 7-35, 10-34, 10-36, 12-4, 12-7, 12-17, 12-22, 12-24, 12-27, 16-19
 - design of, 7-38–7-39, 7-44
 - electrically isolated, 12-3
 - minimal thickness of, 12-4
 - nailing to joists, 7-39
 - plastic, 16-16, 30-48
 - plywood, 7-6, 7-7, 7-9, 7-38, 7-42, 7-43–7-44, 8-53
 - polyethylene, 11-6, 11-21, 11-24, 11-33, 11-46, 12-3, 12-4
 - repair, 12-18
 - slippage, 12-6
 - swelling of, 10-36
- sheet pile, 14-50, 14-52–14-55
- sheeting, *see* sheathing
- Shelby tube, 14-29
- shims, 30-62, 30-63, 30-64, 30-66
 - steel, 30-64
- ships, reinforced concrete, 13-2
- shoots, 5-6
- shop drawings, 12-6, 12-10, 12-38
- shored construction, 10-9–10-10
- shores, 7-5, 7-8, 7-14–7-16, 7-34, 7-38, 8-1–8-19, 8-36, 8-52, 11-32, 11-36, 11-59, 12-9, 12-27, 12-39, 12-41, 27-29, 30-47, 30-64
 - aluminum, 7-14
 - compressible, 8-19
 - demolition, 12-38, 12-41, 12-42
 - design of, 7-41–7-42
 - floor slabs, and, 8-2, 8-7, 8-9
 - for demolition, 11-61
 - horizontal, 7-9
 - jack, 7-14
 - levels of, 8-2, 8-3, 8-4, 8-6, 8-7, 8-9, 8-13, 8-14, 8-19, 8-42, 8-43, 8-52
 - number of per bay, 8-18
 - permanent, 8-53
 - premature removal of, 7-4
 - removal of from flexural members, 8-36, 8-37
 - rigidity of, 8-9
 - temporary, 7-8
 - vertical, 7-21
- shoring and reshoring, 7-14, 8-4, 8-6, 8-7, 8-19, 8-38, 8-41, 8-42, 8-43, 8-49, 8-52, 8-53, 9-15, 9-18–9-19, 12-42
- short-pulse radar, 21-42
- shortening, 11-4, 11-14, 11-19, 11-23, 11-27, 11-32, 11-38, 11-58, 11-60, 12-6, 12-8, 12-28, 12-29, 12-43, 23-13, 35-2, 35-3, 35-4, 35-7–35-8, 35-10, 35-13
 - pile, 14-62
- shot blasting, 23-6–23-8
- shotcrete, 3-17, 11-54, 11-55, 11-60, 14-56, 16-13, 16-15, 20-56, 22-3, 24-12
- shrinkage, 2-15, 4-1–4-2, 4-6, 4-7, 4-10–4-16, 4-18, 4-27, 5-2, 5-30, 5-31, 8-48, 8-49, 8-52, 9-11, 9-13, 9-15, 9-17, 9-18, 9-20, 10-12, 10-23, 10-24, 10-25, 10-26, 11-2, 11-4, 11-15, 11-17, 11-23, 11-30, 11-33, 11-41, 11-42, 12-6, 12-8, 12-10, 12-29, 13-22, 13-25, 15-22, 22-14, 23-2, 23-14, 30-7, 30-15, 30-36, 35-2, 35-3, 36-3

shrinkage (cont.)

- antiwashout admixtures, and, 3-14
 - autogenous, 4-35, 20-22, 20-70, 23-4
 - CEB-FIP model for, 4-16
 - chemical, 21-21
 - silica fume, and, 2-33
 - cracking, 2-34, 3-14, 20-49, 20-51, 28-51, 28-62, 35-2, 35-4
 - creep, and, 8-51
 - deflection, and, 8-49, 8-51, 8-52, 9-4
 - drying, *see* drying shrinkage
 - due to carbonation, 2-15, 4-12
 - high-range water reducers, and, 3-7
 - long-term, 4-34
 - member size, and, 8-30
 - mortar, 28-9
 - overlay, 23-4, 23-12
 - plastic, 5-43, 6-40, 23-4, 23-12, 23-14, 30-58, 30-59
 - prediction, 4-12–4-15
 - reducing admixtures, 3-14
 - reinforcement, 10-17, 17-8
 - relative humidity, and, 8-30
 - slab, 17-13
 - slump, and, 4-16
 - strain, 4-2, 4-3, 4-10, 4-11, 4-13, 4-14, 4-15, 4-16, 4-35, 9-6, 17-2
 - stress, 30-36
 - strips, 17-2
 - thermal, 11-27, 11-50
 - time, and, 8-30–8-31
 - ultimate, 8-29–8-30
 - unreinforced concrete, 8-29–8-31
 - volume/surface ratio, and, 9-6
 - water, and, 4-16
 - water-reducing admixtures, and, 3-4
- side form spacers, 7-14
- side-grain loading, 7-28
- side-sway, 34-4, 36-25
- sieve analysis, of soils, 14-2
- SIFCA®, 22-14
- SIFCON, 22-15, 22-18
- signalers, 19-40
- silane, 5-39, 11-58
 - sealer, 23-14, 35-15
 - surface treatment, 5-38
- silica, 5-23
- silica fume, 1-25, 2-22, 2-23, 2-29–2-38, 3-6, 5-10, 5-27, 5-28, 5-29, 5-38, 5-39, 5-41, 6-8–6-9, 6-18, 6-20, 6-25, 6-32, 9-20, 11-4, 11-5, 11-16, 11-17, 11-23, 11-56, 13-20, 15-20, 22-14, 22-16, 22-17, 23-2, 23-3, 23-14, 23-15, 26-2, 36-1
- air entrainment, and, 2-37
- as-produced, 2-29
- bleeding of, 2-33, 2-34, 2-36
- carbonation, and, 2-32, 2-36
- characteristics of, 2-29–2-30
- chemical composition of, 2-30
- chemical resistance, 2-36–2-37
- compressive strength, and, 2-34–2-35
- condensed, 2-33, 2-37
- cracking of, 2-34
- creep, 2-35
- durability, and, 2-36–2-38
- freeze–thaw resistance, 2-37
- physicochemical mechanisms, 2-30–2-32
- production of, 2-29
- setting time, 2-34
- types of, 2-29
- water demand, 2-32–2-33, 2-34
- workability, 2-33
- silicates, 3-7, 5-27, 6-7, 6-33
- silicon, 2-1, 5-27, 11-5, 24-32, 26-2
- silicon alloys, 2-29

 sulfonated melamine formaldehyde (SMF), 3-5, 6-8
 sulfonated naphthalene formaldehyde (SNF), 3-5, 6-8
 sulfonates, 3-10, 3-11, 6-8
 sulfonic acid esters, 3-5, 6-8
 sulfuric acid resistance, geopolymer concrete SuperBent, 32-59
 superplasticizers, 1-4, 2-27, 2-29, 2-32, 2-34, 2-35, 2-38, 3-2, 3-5, 3-6, 5-30, 5-31, 5-38, 6-5, 6-8, 6-18, 6-21, 6-30, 6-31, 6-32, 6-35, 6-39, 10-23, 10-25, 10-27, 11-5, 11-6, 11-41, 13-22, 13-26, 15-20, 26-3, 26-4, 26-5, 30-19, 30-51, 30-56, 30-72
 first, second, third generations of, 3-5
 vibration, and, 30-56
 super-strength reactive powder concrete, 22-14, 22-16–22-17
 supersulfated cement, 1-10, 1-11
 surface finishes, 3-6, 5-17, 5-43, 7-3
 architectural concrete, 30-12
 robotic application of, 18-2, 18-3–18-5
 surface flatness, 20-34
 surface moisture, 1-17
 surface-penetrating radar (SPR), 16-4, 16-7–16-8
 surface sealers, 5-38, 5-39
 surface temperature, 21-39, 21-40, 21-42
 surface tightness, 20-34
 surface vibrators, 30-53
 surface waves, 21-37–21-39
 surfaced on four sides (S4S), 7-27
 surfactants, 3-10
 surficial materials, 14-1
 sustained load, 4-1, 4-2, 4-4, 4-8, 25-7, 36-3
 sustained modulus, 20-32
 sustained modulus of elasticity, 8-50
 S-waves, 16-4–16-7, 21-31, 21-32, 21-33
 sway frames, 10-15
 sweep representations, 18-9, 18-10
 swelling, 4-10

swelling-strip water stops, 20-51
 synthetic air, 20-20
 synthetic aperture focusing technique (SAFT), 21-31
 synthetic detergents, 3-11

T

tower cranes (cont.)
 dismantling of, 19-27, 19-28
 erection of, 19-27
 freestanding, 19-29
 internal climbing, 19-28–19-29
 transport of, 19-27
 traveling, 19-29
 traveling, 19-22, 19-29
 tower-mounted booms, 19-15, 19-17–19-19
 Trace Parkway Arches, 29-4
 tracking, dozer, 20-66
 traffic barriers, 29-28
 trailer pump, 19-17
 transformed area, 28-3
 transient dynamic response testing, 21-35
 translation, 16-32
 transport stress, 10-39
 transporting concrete, 5-6–5-10, 6-40
 transverse cracking strain, 25-18, 25-19
 transverse force, 32-53
 transverse reinforcement index, 36-28
 travel times, 19-5, 19-6
 traveling speed, crane, 19-34
 tremies, 3-6, 11-14, 15-6, 15-7, 15-8, 15-8–15-9, 30-50
 trial batches, 3-3, 3-4, 3-7, 3-9, 3-18, 6-16, 6-19, 6-23, 6-25, 6-27, 6-29, 6-30, 6-31
 design strength of, 6-17–6-18
 trial-wedge method, 14-47–14-48
 triaxial test, 14-7, 14-8–14-11
 tributylphosphate, 3-12
 tricalcium aluminate, 5-25, 11-4, 13-20, 30-15
 tridymite, 5-40
 triethanolamine, 6-7
 triple-tee, 11-36
 trolleying, 19-26
 speed, 19-34

Civil Engineering

Concrete is one of the most versatile materials of this century and for the next millennium. **The Concrete Construction Engineering Handbook, Second Edition**, provides in-depth coverage of concrete construction engineering and technology. It features state-of-the-art discussions on what design engineers and constructors need to know about concrete, focusing on:

- The latest advances in engineered concrete materials
- Reinforced and prestressed concrete construction
- Specialized construction techniques
- Design recommendations for high performance

In the second edition of the **Concrete Construction Engineering Handbook**, designers, constructors, educators, and field personnel will learn how to produce the best and most durably engineered constructed facilities.

- Encompasses the vital topics necessary for the engineering construction of concrete facilities as well as in-depth coverage of fiber-reinforced plastics (FRP), a new chapter on engineered cementitious composites (ECC), and an extensive new chapter on equipment for building construction
- Includes more than 1,100 tables, charts, graphs, and illustrations presenting many applications in both construction of systems and proportioning materials of construction
- Addresses problems often faced in the design office and in the field pertaining to concrete construction technology, including information on material behavior, design of concrete mixtures, long-term behavior, and high performance qualities of constructed systems
- Covers the latest requirements for structural concrete in accordance with the ACI 318-08 Building Code for flexure, shear, torsion, compression, long-term effects, long columns, and development of reinforcement, as well as the latest IBC 1997 provisions and examples on earthquake design and construction, including the design of precast concrete seismic bracing systems
- Provides in its 36 chapters indispensable information for design engineers, construction engineers, field personnel, researchers in materials, and civil engineering undergraduate and graduate students
- Supplies extensive references at the end of each chapter that direct you to further information on specialized topics

The 37 contributors are world-class leaders in research, design, and construction with a combined professional practice of more than 1,200 years. The wealth of up-to-date knowledge they provide allows you to develop concrete systems that are vastly better, more efficient, and longer enduring.
